## **PREFACE**

The work described herein was executed in fiscal year 2021 as part of the NA-22 Integrated Fuel Cycle Materials and Chemistry Program.

## EXECUTIVE SUMMARY

In fiscal year 2021 (FY21), the Integrated Fuel Cycle Materials and Chemistry Program (IFCMCP) executed numerous tasks related to Task 2, Plutonium Science, including:

- Production and extensive characterization of plutonium (IV) oxalate and its thermal degradation products
  - A manuscript on this work was submitted to Journal of Nuclear Materials (September 2021)
- Production and vibrational spectroscopy characterization of plutonium (IV) nitrate and plutonium (IV) fluoride hydrate.
- Shipment of 325 mg of weapons-grade plutonium dioxide from Savannah River National Laboratory (SRNL) to University of Notre Dame (UND)
- Development of gas-free synthetic methods to produce high-quality anhydrous actinide fluoride samples for use in subsequent characterization measurements.
- Analysis of the relationship between production parameters and physical properties for plutonium (IV) fluoride hydrate produced via aqueous precipitation.
- Graduation of the first UND graduate student supported under this program via the Oak Ridge Fuel Cycle Science Fellowship
- Appointment of the second UND graduate student to be supported under this program via the Oak Ridge Fuel Cycle Science Fellowship.
- Design and fabrication of next-generation spectroscopy containment cells for future experiments involving multiphoton ionization, laser ablation, and liquid analysis.

In this document, FY21 research results are discussed in detail and relevant background information is provided where necessary.

## 1.0 Introduction

Task 2 of the IFCMCP was designed to utilize vibrational spectroscopy, microscopy, X-ray diffraction, and calorimetry to explore the spectroscopic, structural, and chemical properties of plutonium compounds relevant to the nuclear fuel cycle. An important precursor to this work is production of fresh, high-quality plutonium samples. Given the health hazards and material accountability associated with plutonium, sample production is not trivial and production experiments require extensive planning and coordination by research and support staff. Further, because alpha-emissions from plutonium produce time- and dose-dependent radiolysis resulting in structural defects, particularly in the presence of water, freshly prepared plutonium samples must be carefully packaged and analyzed with urgency following their production.

In FY21, SRNL and UND engaged in numerous research studies involving production and subsequent characterization of plutonium dioxide, plutonium fluoride, plutonium oxalate, and plutonium nitrate. Specific efforts involving each of these compounds are described in detail below.

## 2.0 FY21 Progress on Specific Compounds

### 2.1 Plutonium (IV) Oxalate to Plutonium Dioxide

#### 2.1.1 *Background*

Conversion of plutonium (IV) oxalate ( $\text{Pu}(\text{C}_2\text{O}_4)_2$ ) to plutonium dioxide ( $\text{PuO}_2$ ) via high-temperature calcination – a process commonly referred to as the Pu(IV) oxalate method - has been utilized for plutonium processing since the 1940s.<sup>1</sup> Due to its simplicity and dependability, the Pu(IV) oxalate method remains the standard for producing  $\text{PuO}_2$  at industrial-scale nuclear fuel reprocessing facilities.<sup>2</sup> Despite the enduring utility of this method, and the numerous reports written about it, uncertainty abounds regarding the chemicophysical changes that occur during thermal decomposition of  $\text{Pu}(\text{C}_2\text{O}_4)_2$ . In fact, there are at least 8 different reports in the literature whose titles contain both the terms “thermal decomposition” and “plutonium (IV) oxalate”.

While these reports vary in their details, several consistencies have been established. First, Pu(IV) oxalate hexahydrate ( $\text{Pu}(\text{C}_2\text{O}_4)_2 \cdot 6\text{H}_2\text{O}$ ) is the chemical species formed when oxalic acid is mixed with an acidic plutonium (IV) nitrate solution; a result clearly established by powder X-ray diffraction (pXRD) analysis.<sup>3</sup> Second, heating  $\text{Pu}(\text{C}_2\text{O}_4)_2 \cdot 6\text{H}_2\text{O}$  causes dehydration to the plutonium (IV) oxalate dihydrate ( $\text{Pu}(\text{C}_2\text{O}_4)_2 \cdot 2\text{H}_2\text{O}$ ) and eventually anhydrous  $\text{Pu}(\text{C}_2\text{O}_4)_2$ .<sup>3b, 4</sup> Third, isolation of either anhydrous or monohydrate complexes of Pu(IV) oxalate is difficult due to their hygroscopic nature.<sup>4</sup> Fourth, the oxalate ligand decomposes with sufficient heating, eventually leading to the formation of  $\text{PuO}_2$ .<sup>5</sup>

Exact chemical structures of species formed as the oxalate ligand decomposes is an area of uncertainty that still surrounds  $\text{Pu}(\text{C}_2\text{O}_4)_2 \cdot x\text{H}_2\text{O}$  degradation. The most informative descriptions on this topic have derived structural details from geometrically-optimized computational models that, with the exception of  $\text{Pu}(\text{C}_2\text{O}_4)_2 \cdot 6\text{H}_2\text{O}$  and  $\text{Pu}(\text{C}_2\text{O}_4)_2 \cdot 2\text{H}_2\text{O}$  which have published powder XRD patterns, have not been experimentally verified.<sup>3, 6</sup> In fact, a 2021 density functional theory (DFT) study of  $\text{Pu}(\text{C}_2\text{O}_4)_2$  decomposition clearly states that the precise structural modifications occurring during thermal decomposition of  $\text{Pu}(\text{C}_2\text{O}_4)_2$  have not been experimentally characterized, but *the DFT-derived intermediate structures should be identifiable using spectroscopy techniques*.<sup>6a</sup>

With this in mind, our team executed high-resolution Raman and IR spectroscopy measurements on  $\text{Pu}(\text{C}_2\text{O}_4)_2 \cdot 6\text{H}_2\text{O}$  and its degradation products that form up to 450 °C in air. Our experimental setup allowed for collection of high-resolution infrared data under an inert atmosphere using Diffuse Reflectance Infrared Fourier Transform Spectroscopy (DRIFTS) for the Pu-bearing compounds in a double-walled cell. The DRIFTS approach obviates the need for nujol, epoxy resins, or other protective coatings for analyzed specimens. The same material was also analyzed with Raman spectroscopy as Raman spectroscopy is a complementary technique to DRIFTS. The vibrational spectra presented herein provide details of

fundamental importance for these crucial nuclear fuel cycle compounds and can be used in future studies to verify the accuracy of theoretically-derived chemical structures. Considering the ubiquity of the Pu(IV) oxalate method in the nuclear fuel cycle, we believe the publication of these vibrational spectra is long overdue.

### 2.1.2 Synthesis and Thermal Degradation

In a 20 mL scintillation vial,  $\text{Pu}(\text{NO}_3)_4$  (2.1 mL; 0.1 M in 3 M  $\text{HNO}_3$ ; 0.21 mmol) was added dropwise over five minutes to a stirring solution of oxalic acid dihydrate (4 mL; 0.12 M in water; 0.48 mmol, 2.3 eq.). This solution was stirred for two hours during which time tan/dark white solids formed as expected for  $\text{Pu}(\text{C}_2\text{O}_4)_2 \cdot 6(\text{H}_2\text{O})$ ; the solid composition was verified by pXRD (*vide infra*). The suspension was gravity filtered through a filtration apparatus and dried under a positive pressure of argon for 2 hours. Removal of the filter membrane and collection of the tan solid yielded the product as a granular brown solid (See Fig. S1). Yield: 96 mg (87%).

Freshly prepared  $\text{Pu}(\text{C}_2\text{O}_4)_2 \cdot 6(\text{H}_2\text{O})$  solid was divided into six glass vials; five of these were placed into a muffle furnace (Thermo Fisher FB1315M) to undergo heating within a negative pressure radiological glovebox. A heating program was then initiated on the furnace. When establishing a temperature, the furnace set point was set ca. 20 °C below the desired temperature to prevent the temperature of the furnace from exceeding the set point. After the temperature had stabilized, the set point of the furnace was moved to the desired temperature and held for one hour. After one hour, the oven was opened and a vial was removed. The furnace was then raised to the next temperature. This process was performed at 100, 220, 250, 350, and 450 °C. The removed samples were weighed and transferred into sealed glass vials for storage.

### 2.1.3 Characterization Results

The thermal decomposition of  $\text{Pu}(\text{C}_2\text{O}_4)_2 \cdot 6(\text{H}_2\text{O})$  to  $\text{PuO}_2$  was characterized with vibrational spectroscopy (Raman and infrared) and pXRD. Hereafter, all analyzed samples from this study are labeled according to the maximum temperature (in Celsius) at which they were exposed. Thus, the  $\text{Pu}(\text{C}_2\text{O}_4)_2 \cdot 6(\text{H}_2\text{O})$  starting material, which was not heated, is labeled **Pu-25**. Samples heated to 100, 220, 250, 350, and 450 °C are labeled **Pu-100**, **Pu-220**, **Pu-250**, **Pu-350**, and **Pu-450**, respectively. The selected temperatures were derived from previously reported thermogravimetric data which indicated significant mass changes occur near these temperatures.<sup>4</sup> Each of these samples exhibited a unique color that was not well-described in previous literature; therefore, we have provided a photo demonstrating the color of each sample (Figure 2-1).

Raman and IR band positions for all measured samples are provided in Table 2-1. Band assignments were determined by comparison with vibrational spectra of related compounds.<sup>4,7</sup> Acquisition and tabulation of these spectral bands are the most crucial aspect of our study, as these data can be used to assess the accuracy of previously published DFT-derived intermediate structures associated with the Pu(IV) oxalate method.<sup>6a</sup>

Figures Figure 2-2, Figure 2-3, and Figure 2-4 present all pXRD, Raman, and IR measurements. Extensive descriptions on these data are presented in our recently submitted manuscript. The key features of these data that can be summarized as follows:

- Crystalline Pu(IV) oxalate hexahydrate ( $\text{Pu}(\text{C}_2\text{O}_4)_2 \cdot 6\text{H}_2\text{O}$ ) is the chemical species formed when oxalic acid is mixed with an acidic Pu(IV) nitrate solution; a result clearly established by all of our analytical measurements.
- $\text{Pu}(\text{C}_2\text{O}_4)_2 \cdot 6\text{H}_2\text{O}$  has a rich vibrational spectrum with at least 15 Raman and 9 infrared bands between 180 – 2400  $\text{cm}^{-1}$ .
- As  $\text{Pu}(\text{C}_2\text{O}_4)_2 \cdot 6\text{H}_2\text{O}$  is heated to 100 °C, water is liberated to produce crystalline  $\text{Pu}(\text{C}_2\text{O}_4)_2 \cdot 2\text{H}_2\text{O}$ , which also has a rich vibrational spectrum.

- As  $\text{Pu}(\text{C}_2\text{O}_4)_2 \cdot 2\text{H}_2\text{O}$  is heated above 100 °C, the oxalate ligand decomposes to produce amorphous plutonium oxycarbide species and ultimately yielding crystalline  $\text{PuO}_2$  with some residual carbon-containing species when heated to 450 °C
- Small amounts of  $\text{PuO}_2$  were found at calcination temperatures as low as 220 – 250°C. Observation of this result was aided by the ultra-sensitivity of Raman spectroscopy to the  $\text{T}_{2g}$  band of  $\text{PuO}_2$  and the observation of the electronic band at  $2640 \text{ cm}^{-1}$ . The  $\text{PuO}_2$  which forms near 220 – 250 °C appear to be nanoparticulates and future studies into the morphology of these nanoparticulates may prove useful to the Nuclear Forensics community. We are unaware of any previous evidence showing  $\text{PuO}_2$  formation at such low temperatures.

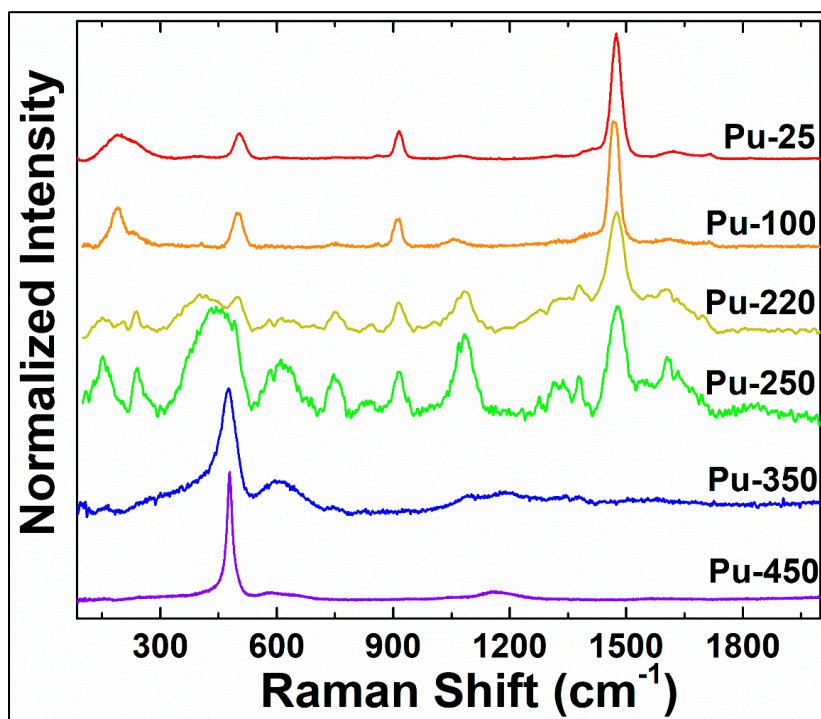

Figure 2-1. Visual appearance of  $\text{Pu}(\text{C}_2\text{O}_4)_2 \cdot 6(\text{H}_2\text{O})$  produced at room temperature (**Pu-25**) and its degradation products up to 450°C (**Pu-450**).

**Figure 2-2.** pXRD patterns of  $\text{Pu}(\text{C}_2\text{O}_4)_2 \cdot 6(\text{H}_2\text{O})$  produced at room temperature (Pu-25) and its degradation products as it is heated to 450 °C (Pu-450).

**Figure 2-3.** Raman spectra of  $\text{Pu}(\text{C}_2\text{O}_4)_2 \cdot 6(\text{H}_2\text{O})$  produced at room temperature (Pu-25) and its degradation products as it is heated to 450 °C (Pu-450).

**Figure 2-4.** IR spectra of  $\text{Pu}(\text{C}_2\text{O}_4)_2 \cdot 6(\text{H}_2\text{O})$  (Pu-25) and its degradation products as it is heated to 450 °C (i.e., Pu-450).

## 2.2 Plutonium (IV) Fluoride Hydrate

### 2.2.1 Background

Pyrochemical preparation of plutonium metal is often carried out by reduction of  $\text{PuF}_4$  or a mixture of  $\text{PuO}_2$  and  $\text{PuF}_4$  in molten salt as shown in equations 2 and 3, respectively. Some processes utilize  $\text{PuF}_3$  as an intermediate leading to  $\text{PuF}_4$  and  $\text{PuO}_2$  as shown in equation 4. Anhydrous plutonium fluoride is typically prepared via high temperature fluorination of plutonium dioxide or oxalates using HF gas. When prepared using aqueous methods,  $\text{PuF}_4$  and  $\text{PuF}_3$  are said to assume hydrated forms of  $\text{PuF}_4 \cdot 2.5(\text{H}_2\text{O})$  and  $\text{PuF}_3 \cdot 0.75\text{H}_2\text{O}$ . Lattice water and plutonium fluorides are both prone to radiolysis from plutonium alpha emissions. The kinetics of  $\text{PuF}_4$  and  $\text{PuF}_3$  radiolysis and the degradation products formed during radiolysis are not currently known. Given its extensive use in the fuel cycle, characterization of radiolytic changes to these fluorides would be an important accomplishment that could provide information about time and method of production as well as proliferation risks

### 2.2.2 Synthesis of Hydrated $\text{PuF}_4$

At the end of FY20, SRNL produced ~100 mg of hydrated plutonium fluoride using the following method.

21.5 mL of the purified 0.1 M  $\text{Pu}(\text{NO}_3)_4$  solution was added to a 100 mL polypropylene beaker along with a magnetic stir bar. The solution was stirred at ~300 revolutions per minute and was maintained at ~25 °C using a heating/stir plate. 9 mL of 1 M HF was carefully added to the solution at a rate of ~3 mL/min using a calibrated positive displacement pump. Immediately following HF addition, the plutonium solution became cloudy and formed a pale pink precipitate that was consistent in appearance with plutonium tetrafluoride hydrate.<sup>8</sup>

The precipitate was filtered and dried under a flow of argon gas for approximately 24 hours. The dried pale pink solids were then collected and isolated in an argon atmosphere to minimize exposure to oxygen and ambient humidity.

Approximately 100 mg of these solids were carefully removed from the radiological glovebox for powder X-ray diffraction analysis of purity and chemical phase. Less than 1 mg of solids were carefully mounted to carbon adhesive tape inside a spectroscopy double-containment cell. The cell was then sealed in an argon environment, removed from the radiological glovebox with assistance from the SRNL Radiation Protection Department, and was delivered to the SRNL Laser Lab for characterization by both DRIFTS and Raman spectroscopy.

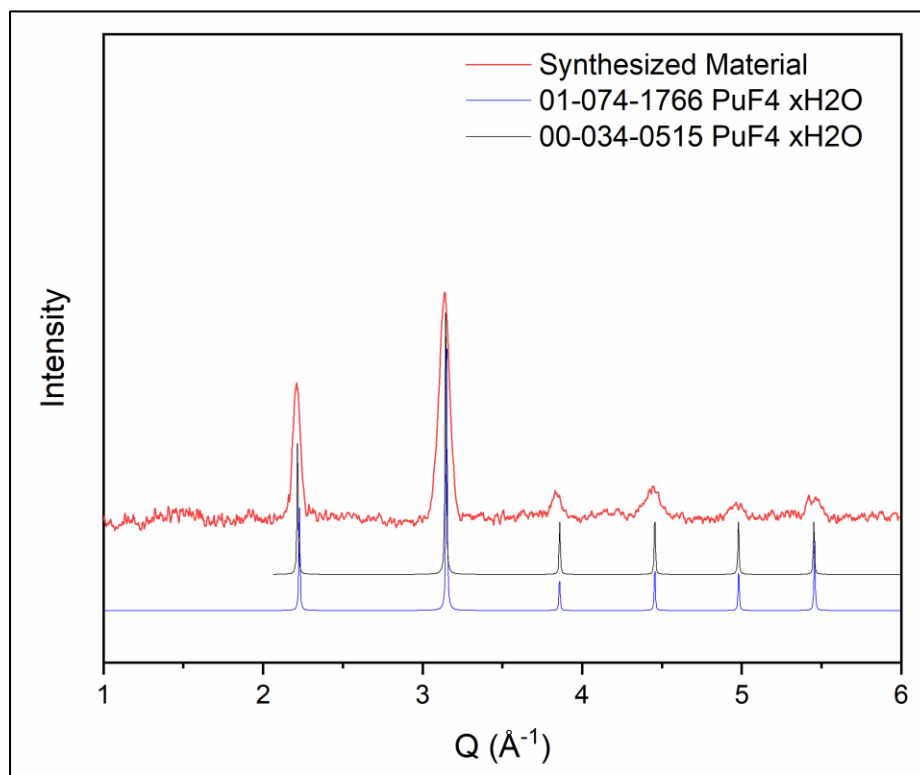

### 2.2.3 Characterization Results

As shown in Figure 2-5, the pXRD pattern for hydrated plutonium fluoride was consistent with the literature pattern for hydrated plutonium (IV) fluoride (PDF 00-034-0515). In general, this compound exhibited very weak diffraction peaks.

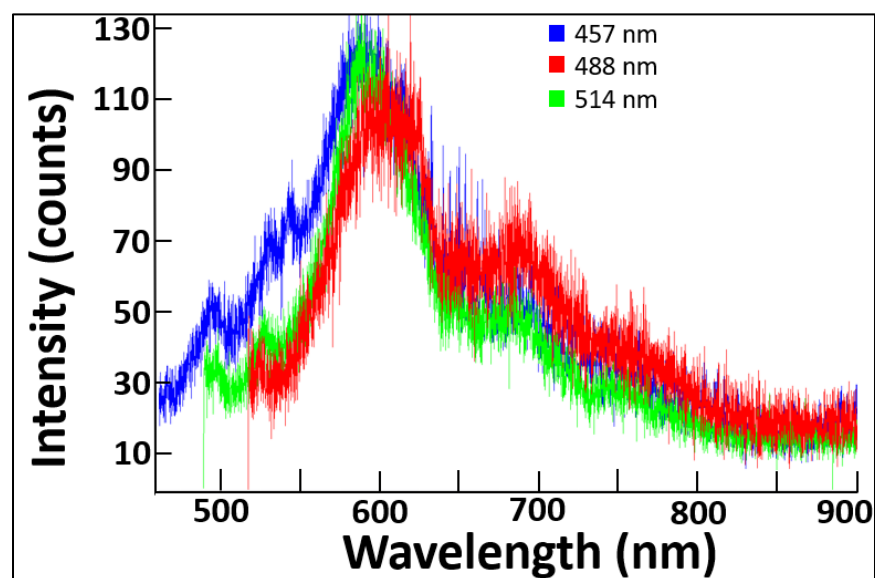

Micro-Raman spectra of the  $\text{PuF}_4$  hydrate were acquired with a LabRAM HR800 UV (Horiba Jobin-Yvon) equipped with an Andor detector (DU146A-LDC-DD) with fringe suppression technology. Four excitation laser wavelengths (458, 488, 514, and 633 nm) were used to help distinguish vibrational modes from fluorescence since fluorescence will vanish when the laser excitation wavelength is changed but the Raman spectral signatures will not.

Similar to the fluorescence observed from  $\text{UF}_4$  and the  $\text{UF}_4$  hydrates<sup>9</sup>, our sample exhibited fluorescence when exposed to each 457, 488, and 514 nm laser wavelengths (Figure 2-6). Although these spectra have not been calibrated for the instrument response, the spectra maxima are located around 600 nm and both the fluorescence and Raman spectra for our sample are very weak in intensity.

**Figure 2-5.** The PDF pattern of hydrated  $\text{PuF}_4$  is displayed with the experimental pXRD pattern for hydrated  $\text{PuF}_4$  solids obtained in our experiments.

**Figure 2-6.** Fluorescence spectra of hydrated  $\text{PuF}_4$  at various excitation laser wavelengths.

Close to the laser excitation wavelength, bands of very weak intensity were observed at 187, 241, 348, 403, 474, and 567  $\text{cm}^{-1}$ . These bands were observed on a rising background toward the laser excitation line and were reproducible at different wavelengths, indicating they did not originate from sample fluorescence. Figure 7 shows these bands acquired at 488 and 633 nm laser wavelengths.

The source of the rising background seen in the spectra in Figure 2-7 does not seem to be fluorescence from  $\text{PuF}_4$  since it persists across multiple laser excitation wavelengths. Instead, the rising background is likely due to a significant number of low-frequency modes from F-F polymeric interactions and the hydrogen bonding from water in the system. Importantly, after examining the spectra of several metal tetrafluoride compounds ( $\text{ZrF}_4$ ,  $\text{HfF}_4$ , and  $\text{CeF}_4$ ) in 1975, Goldstein *et al.*<sup>10</sup> postulated these compounds have a three-dimensional polymeric structure instead of the simplistic tetrahedral structure originally theorized by Krasser *et al.*<sup>11</sup> Although Goldstein *et al.* were unsuccessful in measuring the  $\text{UF}_4$  Raman spectrum due to material decomposition, Villa-Aleman and Wellons successfully measured the spectrum in 2016<sup>9</sup> to confirm Goldstein's argument of a three-dimensional polymeric structure for some metal tetrafluorides, like  $\text{UF}_4$ . Based on the spectra in Figure 2-7, specifically the rising background, we suspect that  $\text{PuF}_4$  has a similar polymeric structure; however, further studies with higher resolution are still needed to confirm this hypothesis.

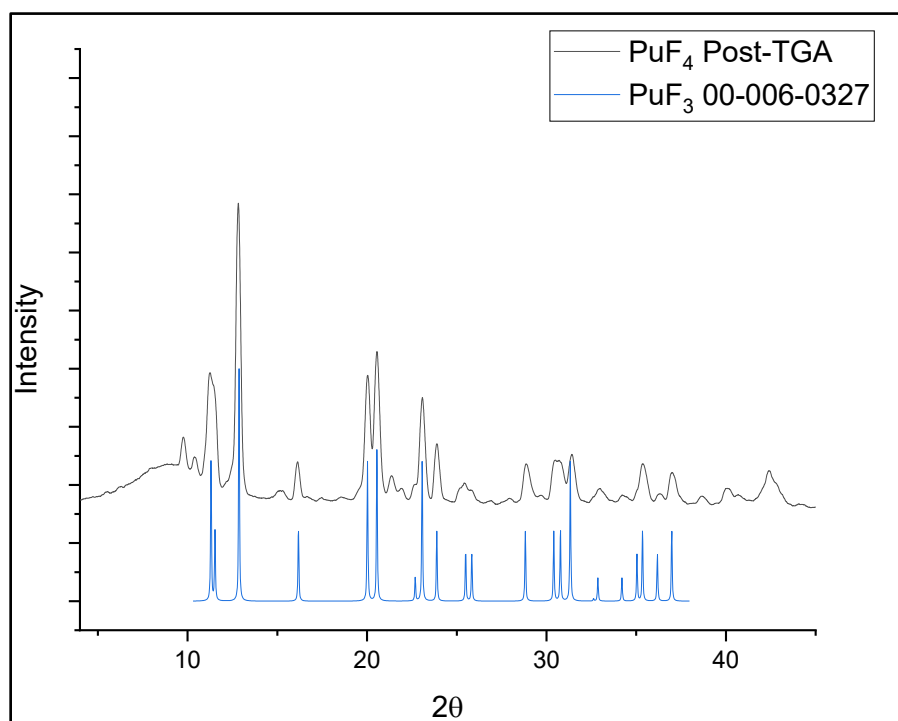

**Figure 2-7.** Raman spectra of hydrated  $\text{PuF}_4$  when interrogated with a 633 and 488 nm excitation laser.

An issue with collecting high-fidelity Raman spectra on hydrated  $\text{PuF}_4$  is that the intensity of the resultant Raman bands is extremely low and very few bands are observed (as compared to the Raman spectrum of  $\text{UF}_4$ ). We postulated that this was due to low crystallinity of the material. The solubility of  $\text{PuF}_4$  is extremely low in water, and the material immediately precipitates from solution once a fluoride source is added. Rapid precipitation such as this likely precludes crystallite growth yielding amorphous or weakly crystalline powders. In an effort to improve crystallinity, we annealed the sample at 200 °C and repeated Raman and pXRD measurements. Unfortunately, the material appeared unchanged by the annealing process.

To better understand the thermal stability of this material, we performed multiple thermogravimetric analysis (TGA) measurements. As shown in Figure 2-8, a total mass loss of ~6.54 wt.% was observed when the material was heated to 800 °C in argon. Post-TGA pXRD showed that the final product after heating to 800 °C was  $\text{PuF}_3$  (Figure 2-9). In summary, attempts to produce anhydrous  $\text{PuF}_4$  or larger crystallites of hydrated  $\text{PuF}_4$  by heating hydrated  $\text{PuF}_4$  were unsuccessful and heating hydrated  $\text{PuF}_4$  eventually leads to conversion to  $\text{PuF}_3$ .

**Figure 2-8.** TGA data of hydrated  $\text{PuF}_4$  analyzed under an argon atmosphere

**Figure 2-9.** Powder on SC-XRD pattern for post-TGA material (black trace), which is consistent with the PDF card for  $\text{PuF}_3$  (blue trace).

To confirm our suspicion that crystallite size is extremely small in precipitated  $\text{PuF}_4$  hydrate, we measured the size of the precipitate with scanning electron microscopy (SEM). As shown in Figure 2-10, the solids formed by precipitation of  $\text{PuF}_4$  hydrate are indeed extremely small. Thus, we can conclude the precipitation of  $\text{PuF}_4$  hydrate occurs too fast to produce a highly crystalline material that would be amenable

towards advanced spectroscopic characterization. Efforts to increase crystallite size via thermal annealing proved unsuccessful up to 200 °C, and efforts are currently on-going to grow larger crystallites in solution.

**Figure 2-10.** SEM micrographs of precipitated PuF<sub>4</sub> hydrate show the material consists of extremely small particulates.

Recognizing the difficulty in producing quality samples of PuF<sub>4</sub> and PuF<sub>4</sub> hydrate, the University of Notre Dame team began investigating novel synthetic techniques for producing these materials as described below in Section 2.3

## 2.3 Novel Synthesis Techniques for Producing Actinide Fluoride Samples

### 2.3.1 *Background*

Anhydrous actinide fluoride materials are typically prepared via high temperature fluorination of actinide oxides or oxalates using HF gas. Unfortunately, high temperature fluorination poses a number of safety hazards and is largely prohibited in many research facilities. This means that high quality samples of actinide fluorides can be difficult to acquire. In fact, the only recent paper published on PuF<sub>4</sub> appeared in 2017 from McCoy *et al.* at PNNL.<sup>12</sup> The sample used by this team was a forty year old PuF<sub>4</sub> sealed source that was used in the Plutonium Finishing Plant from 1970 – 2010. Although PuF<sub>4</sub> can be prepared by fluoride precipitation from aqueous solution, synthesis of a high-fidelity, crystalline sample of PuF<sub>4</sub> in this fashion poses several scientific challenges (as described in Section 2.2).

Recently, new synthetic methods have appeared in the literature for producing UF<sub>4</sub> without high temperature corrosive gas.<sup>13</sup> Recognizing the possible utility of these methods to produce high quality PuF<sub>4</sub> specimens that would be amenable towards subsequent characterization studies, our team attempted to adapt these synthetic methods to Pu. These experiments occurred at the University of Notre Dame and were mainly performed with CeO<sub>2</sub> and UO<sub>2</sub> as surrogates for PuO<sub>2</sub> in FY21. This surrogate work allowed our team to develop robust procedures for handling fluorinated actinides prior to manipulating radioactive Pu samples.

### 2.3.2 *Attempted Synthesis of Anhydrous CeF<sub>4</sub> (PuF<sub>4</sub> surrogate) with XeF<sub>2</sub>*

Attempts to synthesize anhydrous CeF<sub>4</sub> were performed following the approach by Inabinett *et al.* (i.e., fluorination using XeF<sub>2</sub>).<sup>13a</sup> Briefly, excess molar ratios of CeO<sub>2</sub> and XeF<sub>2</sub> were placed in a perfluoroalkoxy (PFA) vial under nitrogen atmosphere in a negative-pressure glovebox. The vial was transferred to a Parr reaction vessel and was heated for varying lengths of time (5–24 hrs) and at varying temperatures ( $\leq 205$  °C).

### 2.3.3 *Successful Synthesis of Anhydrous UF<sub>4</sub> with an Ionic Liquid*

Anhydrous UF<sub>4</sub> was synthesized following the approach reported by Florian *et al.* (2020), which uses the ionic liquid 1-Butyl-3-methylimidazolium hexafluorophosphate, [BMIM][PF<sub>6</sub>].<sup>13b</sup> For the synthesis, 40 mg of UO<sub>2</sub> and 2 ml of [BMIM][PF<sub>6</sub>] were placed in a Teflon reactor under nitrogen in a negative-pressure glovebox. The reactor was then placed in a Parr reaction vessel and heated at 180 °C for 96 hours. The green powder of UF<sub>4</sub> was noticeable upon centrifugation and after washing with CH<sub>2</sub>Cl<sub>2</sub>. Powder X-ray diffraction by single crystal matches perfectly with the powder patterns reported Florian *et al.* (2020) and with PDF card # 01-082-2317 (anhydrous UF<sub>4</sub>). Thermal gravimetric analysis (TGA) confirms UF<sub>4</sub> to be anhydrous. To meet the three layers of containment necessary for Pu, a recent UF<sub>4</sub> synthesis attempting the use of perfluoroalkoxy (PFA) vials in a Parr reaction vessel with no water has also proven to be successful.

### 2.3.4 *Results*

As described above, numerous synthesis experiments were attempted using CeO<sub>2</sub> and XeF<sub>2</sub>. Thus far, we hypothesize that the quarter inch of water necessary for Parr reaction vessels to interact with the starting material results in the formation of CeF<sub>4</sub>·0.9H<sub>2</sub>O with minor side products. To avoid hydration of the material, alternative closed systems, such as glass ampules and Swagelok tubes, were explored. Powders from glass ampules resulted in CeF<sub>3</sub> and a mixed phase of starting material with CeF<sub>3</sub>. Synthesis attempts involving Swagelok tubes resulted no change to the starting materials.

The most promising results from these experiments so far were achieved when XeF<sub>2</sub> was mixed and heated with CeO<sub>2</sub> at a 6:1 ratio at 130 °C for 10 hours (Figure 2-11) and a 5:1 ratio at 150 °C for 10 hours (Figure 2-12). In both cases, the dominant chemical phases appear to be CeF<sub>4</sub> and CeF<sub>3</sub> although some byproducts (hydrates and CeO<sub>2</sub>) persist. Notably, CeO<sub>2</sub> appears to be absent from the pXRD pattern resulting from the 5:1 XeF<sub>2</sub>:CeO<sub>2</sub> reaction. University of Notre Dame will continue experiments with XeF<sub>2</sub> in FY22.

**Figure 2-12.** (Green trace) pXRD of solids obtained after mixing  $\text{XeF}_2$  and  $\text{CeO}_2$  (5:1 ratio) for 10 hours at 155 °C. (Red trace) The database PDF pattern for  $\text{CeF}_4$  (04-007-3514)

A significant accomplishment by the Notre Dame team was the successful synthesis of anhydrous  $\text{UF}_4$  using the ionic liquid  $[\text{Bmim}][\text{PF}_6]$ .<sup>13b</sup> In FY22, UND will attempt to adapt this method to cerium and plutonium. If successful, we expect the production of high quality  $\text{PuF}_4$  to have a major impact on our future efforts to characterize nuclear fuel cycle materials. In fact, there are at least two dozen publications in the literature pertaining to  $\text{UF}_4$  and we propose that many of these studies could be reproduced with  $\text{PuF}_4$ .

## 2.4 $\text{Pu}(\text{NO}_3)_4$

### 2.4.1 Background

The majority of liquid-based plutonium processing operations occur in nitric acid. Thus, plutonium nitrate is a major component used in the nuclear fuel cycle.

### 2.4.2 Synthesis of $\text{Pu}(\text{NO}_3)_4$

Weapons-grade (~93% Pu-239) plutonium dioxide ( $\text{PuO}_2$ ) was heated for several hours at ~100 °C in a mixture of 8 M nitric acid and a minimal amount (~0.5 M) of sodium fluoride to afford dissolution of the material. This solution was purified using an anion exchange column loaded with a commercial, positively charged, quaternary amine strong base resin, Reillex HPQ. The column was rinsed twice with 8 M nitric acid before introducing the 8 M plutonium nitrate solution. When dissolved in  $\text{HNO}_3$  (between 7 – 9 M), plutonium is primarily in the hexanitrate form,  $\text{Pu}(\text{NO}_3)_6^{2-}$ , which has a high affinity for the Reillex HPQ resin. Most other elements do not form stable anionic complexes at such high nitric acid concentrations and as such have very little affinity for resin. Purified plutonium nitrate,  $\text{Pu}(\text{NO}_3)_4$ , was eluted using dilute ( $\leq 1$  M) nitric acid.

The eluted solution was adjusted to ~1 M  $\text{HNO}_3$  and was analyzed for plutonium concentration using gamma spectroscopy. The plutonium concentration was measured as ~0.1 M.

A 1 mL aliquot of the purified  $\text{Pu}(\text{NO}_3)_4$  solution was added to a vacuum flask and was dried under reduced pressure for approximately 5 hours. The resultant product was a green, sludge-like substance that was then further dried under argon to produce solid  $\text{Pu}(\text{NO}_3)_4$ .

### 2.4.3 Results

Raman measurements of  $\text{Pu}(\text{NO}_3)_4$  were quite rich, showing at least a dozen bands between 100  $\text{cm}^{-1}$  and 2000  $\text{cm}^{-1}$  (Figure 2-13). Additional characterization of this material along with assigning bands is scheduled for FY22.

**Figure 2-13.** Raman spectrum of solid  $\text{Pu}(\text{NO}_3)_4$ .

### 3.0 Conclusions

In FY21, SRNL and UND engaged in numerous research studies involving production and subsequent characterization of plutonium dioxide, plutonium fluoride, plutonium oxalate, and plutonium nitrate. Vibrational spectroscopy, microscopy, X-ray diffraction, and thermogravimetric analysis were used to explore the spectroscopic, structural, and chemical properties of these plutonium compounds. Although largely fundamental in nature, the results presented herein shine new light on the properties of many of these compounds and should have utility in improving plutonium nonproliferation efforts.
