Modeling Phase Equilibrium of Common Sugars

Glucose, Fructose, and Sucrose in Mixed Solvents

TABLE OF CONTENTS FIGURE:

ABSTRACT

The industrial processing of sugars and sugar-containing mixtures is gaining widespread use as a form of renewable manufacturing from biomass. To aid in process modeling for design and optimization, a commonly available thermodynamic model is needed that describes the phase equilibrium of these compounds. This work compiles and compares models for solid-liquid and vapor-liquid phase equilibrium from the available data for the representative sugars glucose, fructose, and sucrose in the representative solvents water, methanol, and ethanol, including data for multi-sugar, multi-solvent systems. The Non-random Two liquid (NRTL) model was chosen for these systems because of its widespread use in industry and the availability of parameters for many solvents and co-solutes. The association-NRTL (aNRTL) model was investigated as an improvement for modeling sugars, which may experience a high degree of association due to their many hydroxy groups. Both models accurately capture the data and are able to predict the behavior of multi-sugar systems with only solute-solvent interaction parameters. The aNRTL model shows an improvement over the baseline NRTL model that is most significant for sucrose, the component with the highest association strength, and least significant for fructose, which has the lowest association strength.

INTRODUCTION

The processing of sugars has long been of interest to chemical engineering, but for the most part that interest has been relegated to the food industry.¹ More recently, the processing of biomass into useful chemical precursors has come to the fore as a way to reduce our reliance on nonrenewable resources.² With the rapid expansion of this field, it is necessary to develop a thermodynamic model for industrial processing of these biomass products that can be easily incorporated within the existing process modeling framework.

Many processes that convert biomass to useful products begin with pyrolysis, followed by refining of the resulting bio-oils, vapors and aerosols.³ Sugars are important products of bioprocessing refineries since they can be used to generate products like cellulosic ethanol (EtOH) and bio-based chemicals. Very little deoxygenation occurs during pyrolysis, resulting in bio-oil with elemental composition closely resembling the original biomass.⁴ Bio-oil contains a wide variety of oxygenated functional groups that are highly reactive, promoting esterification, condensation, polymerization, and other reactions that contribute to the instability of bio-oil in storage.⁵

To overcome that problem, it is necessary to submit the products to a series of separation steps to remove reactive contaminants and purify the desired product. Rover et al.⁶ have demonstrated a pyrolysis product refining process that involves several stages manipulating the phase equilibrium of the sugar-rich, high-boiling product referred to as heavy bio-oil. The steps of this process are outlined in **Figure 1**. Of particular interest are the liquid-liquid extraction and crystallization steps, which make use of the differing solubility of the various components in water and other solvents. Development of a thermodynamic model compatible with industrial process simulation is necessary to facilitate the design and optimization of bio-oil refining processes. It is preferable to use one for which the parameters of the other components in bio-oil are already well-defined.

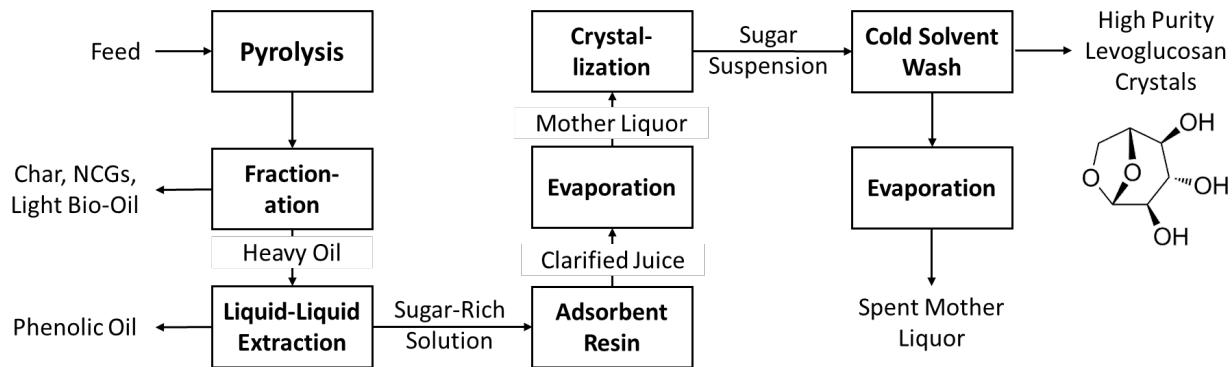

Figure 1: Schematic of a pyrolysis product refining process, adopted from Rover et al.⁶

This work focuses on the phase equilibrium analysis of the three representative sugars glucose, fructose, and sucrose in solvent mixtures of water, methanol (MeOH), and EtOH. At low to moderate pressures, vapor-liquid and solid-liquid equilibrium (VLE and SLE) mostly depend on the activity of the liquid phase. Thus, an activity coefficient model is necessary to describe phase equilibrium in these systems of interest.

Many researchers have proposed activity or osmotic coefficient models for sugars dissolved in water and other solvents. Several sources used their own empirical models, usually in the form of a polynomial series.⁷⁻¹¹ These can be very accurate but tend to fit only the data from which they are derived and are not easily applicable to other conditions or systems. The most common models used are UNIFAC and its derivatives¹²⁻¹⁷ and UNIQUAC and its derivatives^{13, 15, 18-23}. These models tend to be accurate, although those with better fits^{13-18, 20-23} introduce modifications to the original UNIFAC and UNIQUAC models for which there may not be parameters available for extensions to other systems. Once again, most of these models are derived from one or a few sets of data, and so might not reflect the full range of data collected for these systems. For example, Gong et al.¹³ compared predictions by the modified UNIQUAC, S-UNIFAC, and mS-UNIFAC models for glucose, fructose, and sucrose in water-EtOH mixtures. They restricted their data set to solubility only, using their own experimental data and most (but not all) of the solubility data

available at the time.^{15, 21-22, 24} The modified UNIQUAC model performed well, but was restricted to the temperature range of 273.15 to 293.15 K. The accuracy of the model was not investigated for other forms of phase equilibrium, such as VLE.

The Non-random Two-liquid (NRTL) model²⁵ was chosen for this work because of its proven record of dealing with highly nonideal systems and widespread use in the chemical industry. Consequently, most solvents and common co-solutes encountered already have well-defined parameters. Because of the similar chemical nature of sugars, the sugar-sugar interactions in mixed-sugar solutions should be relatively ideal. Therefore, regressing sugar-solvent binary parameters should allow the model to be easily extended to systems with any number of dissolved sugars. The association-NRTL (aNRTL) model²⁶ is an extension of the NRTL model that specifically accounts for associating species, making it particularly well-suited for water, alcohols, and sugars that exhibit high degrees of hydrogen bonding due to an abundance of hydroxyl groups. It introduces two to three new component-specific parameters, increasing the predictive capability of the model without requiring any more data.

PHASE EQUILIBRIUM MODELING

At low to moderate pressures, both VLE and SLE are controlled by the activity of species in the liquid phase. As sugars can be damaged by high temperatures and pressures, an accurate activity coefficient model is the key to modeling separations processes involving these species.

The NRTL model²⁵ calculates the activity coefficient of species i in a mixture, γ_i , as a function of its mole fraction, x_i by the equation:

$$\ln \gamma_i = \frac{\sum_j \tau_{ji} G_{ji} x_j}{\sum_k G_{ki} x_k} + \sum_j \frac{x_j G_{ij}}{\sum_k x_k G_{kj}} \left(\tau_{ij} - \frac{\sum_m x_m \tau_{mj} G_{mj}}{\sum_k x_k G_{kj}} \right) \quad (1)$$

where

$$G_{ij} = \exp(-\alpha_{ij}\tau_{ij}), \quad (2)$$

τ_{ij} is the binary interaction parameter of species i and j , and the non-randomness factor, α_{ij} is fixed at a constant value (usually around 0.3). In this case, the binary interaction parameter is given the temperature dependency:

$$\tau_{ij} = a_{ij} + \frac{b_{ij}}{T} \quad (3)$$

Temperature-dependent NRTL binary interaction parameters for the water and alcohol solvents are included in **Table 1**.

Table 1: Solvent NRTL binary interaction parameters from the Aspen Properties databank.²⁷

Comp. i	Comp. j	a_{ij}	b_{ij}/K	a_{ji}	b_{ji}/K	$a_{ij} = a_{ji}$	$\tau_{ij}(298K)$	$\tau_{ji}(298K)$
Water	EtOH	3.46	-586	-0.80	246	0.3	1.492	0.025
Water	MeOH	2.73	-617	-0.69	173	0.3	0.662	-0.113
MeOH	EtOH	4.71	-1162	-2.31	484	0.3	0.814	-0.690

The NRTL model has been further improved to better describe highly associating systems with the addition of an association term.²⁶ The activity of component i in the aNRTL model is described by the equation:

$$\ln \gamma_i = \ln \gamma_i^{Resid} + \ln \gamma_i^{Comb} + \ln \gamma_i^{Assoc} \quad (4)$$

The residual term, $\ln \gamma_i^{Resid}$, is calculated with the original NRTL equation (Equation 1). The combinatorial term, $\ln \gamma_i^{Comb}$, uses a modified Flory-Huggins expression:²⁸

$$\ln \gamma_i^{Comb} = 1 - \frac{\varphi'_i}{x_i} + \ln \frac{\varphi'_i}{x_i} \quad (5)$$

where φ'_i is the modified volume fraction:

$$\varphi'_i = \frac{r_i^{\gamma_3} x_i}{\sum_j r_j^{\gamma_3} x_j} \quad (6)$$

and r_i is the molecular Van der Waals volume that may be calculated from Bondi's group-contribution method.²⁹ The association term, $\ln \gamma_i^{Assoc}$ was derived by Ferreira et al.^{26, 30} from Wertheim's theory:

$$\ln \gamma_i^{Assoc} = \sum_A v_i^A \left[\ln \left(\frac{X^A}{X_i^A} \right) + \frac{X_i^A - 1}{2} \right] + r_i \sum_A \rho_A \left(\frac{1 - X^A}{2} \right) \quad (7)$$

where:

$$X^A = \frac{1}{1 + \sum_B \rho_i^B \Delta^{AB} X_i^B} \quad (8)$$

$$X_i^A = \frac{1}{1 + \sum_B \rho_i^B \Delta^{AB} X_i^B} \quad (9)$$

$$\rho^A = \frac{\sum_j v_j^A x_j}{\sum_j r_j x_j} \quad (10)$$

$$\rho_i^A = \frac{v_i^A}{r_i} \quad (11)$$

Here ν_i^A is the number of sites of type A in component i ; X^A and X_i^A are the unbounded site fractions of type A in the solution and in pure component i , respectively; and ρ^A and ρ_i^A are the dimensionless molar density of site type A in the solution and in pure component i . The index B in Equations 8 and 9 refers to the sites which associate with sites of Type A , so the definitions of ρ^B , ρ_i^B , and ν_i^B are analogous to those of ρ^A , ρ_i^A , and ν_i^A .

In this work, we follow the convention of Hao and Chen³¹ and look at the association strength from hydrogen bonding. The two types of sites are thus labeled A (hydrogen bond Acceptor) and D (hydrogen bond Donor). The dimensionless association strength, Δ^{AD} , can be approximated as a function of the specific association strength parameters, δ^A and δ^D , and a reference association strength, Δ_{ref}^{AD} :

$$\Delta^{AD} = \frac{\delta^A}{\delta_{ref}^A} \frac{\delta^D}{\delta_{ref}^D} \Delta_{ref}^{AD} \quad (12)$$

where the reference association strength parameters, δ_{ref}^A and δ_{ref}^D are both set to 1. The reference association strength is that of the self-association of water, which, according to Mengarelli et al.,³² can be modeled as:

$$\Delta_{ref}^{AD} = \kappa_{ref}^{AD} \left[\exp \left(\frac{\varepsilon_{ref}^{AD}}{kT} \right) - 1 \right] \quad (13)$$

where κ_{ref}^{AD} is the dimensionless characteristic association volume and ε_{ref}^{AD} is the association energy between the reference acceptor and donor sites. For water, their values are $\kappa_{ref}^{AD} = 0.034$ and $\frac{\varepsilon_{ref}^{AD}}{k} = 1960$ K.³¹ The association parameters for the three solvents used in this study were

taken from the literature³¹ and are included in **Table 2**. The residual term parameters were regressed from available experimental data^{27, 33} and are included in **Table 3**.

Table 2: Solvent association parameters.³¹

Solvent	v_i^A	v_i^D	δ_i^A	δ_i^D	r_i
Water	2	2	1	1	0.76
MeOH	2	1	1	1	1.43
EtOH	2	1	1	1	2.11

Table 3: Solvent aNRTL residual term parameters regressed from data available in NIST databank.^{27, 33}

Comp. <i>i</i>	Comp. <i>j</i>	a_{ij}	b_{ij}/K	a_{ji}	b_{ji}/K	$a_{ij} = a_{ji}$	$\tau_{ij}(298K)$	$\tau_{ji}(298K)$
Water	EtOH	5.19	-1332	-3.91	1128	0.2	0.72	-0.127
Water	MeOH	1.20		-0.58		0.2	1.20	-0.577
MeOH	EtOH	-10.22	3499	8.92	-3027	0.2	1.52	-1.234

Solubility is modeled with the equation:

$$K_{sp,i} = \frac{\gamma_i x_i^L}{a_i^S} \quad (14)$$

where x_i^L is the mole fraction of species *i* in the liquid phase and $a_i^S = 1$ is the activity of *i* in the solid phase. The solubility constant is given the temperature dependence:

$$\ln K_{sp} = a + \frac{b}{T} \quad (15)$$

AVAILABLE EXPERIMENTAL DATA

A thorough examination of the literature found a range of data types including osmotic coefficient (water activity), vapor pressure, boiling point, and solid solubility. The solvents water, MeOH, and EtOH were chosen in order to account for polar and nonpolar interactions as well as varying degrees of association. The availability of data was also considered, so that each sugar is adequately represented in all three solvents. The most comprehensive literature survey and modeling effort for glucose, fructose, and sucrose in these solvents was performed by Peres and Macedo in 1996.²⁰ They continued to update their model with their own experimental data until 2001,¹⁵ but other studies conducted since then have shed further light on these systems. Starzak and Mathlouthi¹¹ performed a very comprehensive literature survey for sucrose-water solutions as part of their modeling efforts, which was used as a starting point for that system in this work.

Table 4, **Table 5**, and **Table 6** summarize the data, including the data type, temperature range, pressure range, number of data points, and source(s).

The references marked with an asterisk (*) were considered outliers and, therefore, excluded from the regression. Including data from any one of these sources was observed to increase the mean squared error of the associated regression by an order of magnitude. This could have been due to a variety of reasons. The most common justification for excluding a source of solubility data was that it likely included a metastable sugar hydrate, such as glucose·monohydrate ($C_6H_{12}O_6 \cdot H_2O$)³⁴, in the solid phase that was not specified in the solid phase composition. There are a few sources that measure the solubility of glucose^{7, 35-37}, fructose³⁸, and sucrose³⁹ hydrates. These tend to appear at low temperatures and at high water concentrations, and so are not common in the systems studied here. For the purpose of modeling the activity of these sugars in solution, the most common solid phase provides more than sufficient data. For each source excluded, at least two

other data sources of the same type were included, so excluding one data source did not create a gap in model fitting.

The majority of sources do not report uncertainties, so they were assigned based on the variable type. Typical values are 0.1 K for temperature, 0.1 kPa for pressure, 0.005 mole/mass fraction for composition, and 0.005 units for activity coefficient. These standard values were subject to increase by a factor of 2 to 5 in certain cases when the quality of the data was uncertain, or the reported measurements did not have sufficient significant digits. A more thorough discussion of the assignment of standard deviations is included in the Supporting Information.

MODEL RESULTS

All available data for single sugars, excluding certain sets as discussed above, were used to regress the necessary parameters for each sugar and each model in turn – temperature-dependent K_{sp} , temperature-dependent τ_{ij} for each model, and δ^A , δ^D , and r for the aNRTL model – simultaneously, using the regression tool built into Aspen Properties V11.²⁷ The parameters were all regressed together to get the most accurate result for the sugar-specific solubility (K_{sp}) and association (δ^A , δ^D , r) parameters. Aspen Properties reports two statistics for its regressions. The residual root mean squared error ($RMSE$) is defined as:²⁷

$$RMSE = \sqrt{\frac{WSS}{K - n}}$$
(16)

where K is the total number of data points, n is the number of parameters, and the weighted sum of squares (WSS) is defined as:

$$WSS = \sum_{l=1}^g w_l \left[\sum_{i=1}^k \sum_{j=1}^m \left(\frac{Z_{ij} - ZM_{ij}}{\sigma_{ij}} \right)^2 \right]$$
(17)

ZM_{ij} is the measured data, Z_{ij} is the calculated value, σ_{ij} is the standard deviation assigned to the data point, w_l is the weighting factor assigned to the data group, l is the data group number, g is the total number of data groups, i is the data point number, k is the total number of data points within data group l , j is the measured variable (T , P , x , etc.) number, and m the total number of variables associated with data point i .

While RMSE uses the number of parameters to penalize overfitting of the data, there are additional statistical tests that are more sensitive to superfluous parameters such as the Mallows,⁵⁸ Akaike, and Bayesian information criteria,⁵⁹ which balance the likelihood function against the number of parameters. When tested, they were found to give similar results qualitatively. Consequently, only the Bayesian information criterion (BIC) is reported in this paper since it appeared to be the most sensitive to overfitting of the data. The BIC is defined as:

$$BIC = K \ln \left(\frac{SSE}{K} \right) + n \ln K$$
(18)

where SSE is the sum of the squared errors. Since Aspen Properties only reports the WSS , it was more practical to replace SSE in Equation (18) with WSS as defined in Equation (17). This can be

justified for a qualitative comparison of two models derived from the same data set, since the weighting factors w_l and σ_{ij} is identical for both cases. The weighting of the error makes it more likely for WSS to be less than K , resulting in a negative value of the modified *BIC*. When looking at two models derived from the same set of data, the preferred model is the one with the lower (more negative) value of modified *BIC*. The exact values of the statistical parameters, along with a discussion of the process for assigning standard deviations to experimental data, is included in the Supporting Information. **Table 8** shows the association parameters regressed for each sugar, along with the values of RMSE and modified BIC for the NRTRL and aNRTL models. The values of ν_i^A and ν_i^D for each sugar were chosen based on the number of available hydrogen bond acceptor and donor sites on the hydroxy groups of each sugar. The structure of the most common form of each sugar can be seen in **Figure 2**.

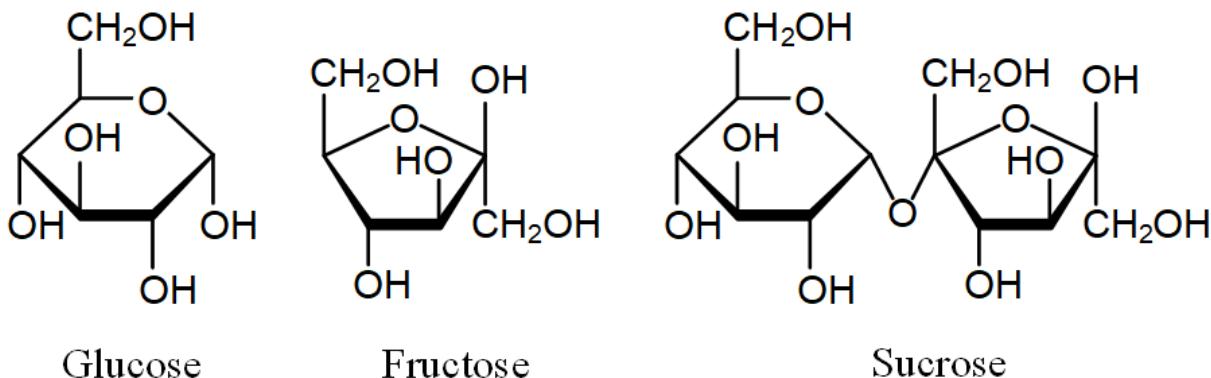

Figure 2: Molecular structure of the three representative sugars.

In each case, the aNRTL model is a significant improvement over the base NRTL model. This improvement is most pronounced for sucrose, which has the highest number of associating hydroxy groups and the highest association strength, and least significant for fructose, which has the lowest estimated association strength. One possible explanation for the low association strength of fructose is the size of the molecule. As a furanose ring, its hydroxy groups are closer

together than those of glucose or sucrose, and the two methylene groups result in a higher degree of flexibility than is found in glucose. This configuration could result in a high degree of intramolecular association, resulting in the low observed association strength with external sites. The parameter r_i was included in the regression, in every case reflecting a reduction from that estimated using Bondi's group contribution method²⁹ (8.46 for glucose, 7.69 for fructose, and 14.31 for sucrose). Fixing r_i results consistently in a drastic increase in *RMSE* and modified *BIC* compared to the baseline NRTL and aNRTL with variable r_i models. While the r_i in the combinatorial term of aNRTL has a definite physical significance, that term has only a small effect on the activity calculations, while the r_i of the association term is more open to interpretation. This should be carefully considered as the aNRTL model is extended further, but that is beyond the scope of the present work. Still, it can be hypothesized that a reduction in r_i for large, complex molecules with many association sites may better reflect the actual size of these molecules in solution, which could be expected to decrease when the effects of relatively strong association are spread over the large number of association sites. This hypothesis is supported by the trend of fructose having the lowest association strength and the least reduction in r_i .

Table 8: Regressed association parameters for the three sugars and *RMSE* and modified *BIC* for the NRTL and aNRTL models.

Sugar	v_i^A	v_i^D	δ_i^A	δ_i^D	r_i	<i>RMSE</i>	Modified <i>BIC</i>		
						(NRTL)	(aNRTL)	(NRTL)	(aNRTL)
Glucose	10	5	1.31 ± 0.09	0.07 ± 0.02	4.90 ± 0.29	0.94	0.85	-7	-94
Fructose	10	5	0.07 ± 0.02	0.00 ± 0.00	4.65 ± 0.25	0.98	0.88	32	-36
Sucrose	16	8	2.00 ± 0.06	0.80 ± 0.20	9.54 ± 0.31	0.70	0.51	-186	-381

Table 9 and **Table 10** present the NRTL model and aNRTL residual binary interaction parameters for each of the three sugars in each of the three solvents, as well as the K_{sp} solubility parameter for the solid sugars associated with each model. The τ parameters show a consistent trend between the two models, with the τ_{ij} increasing from negative to positive from water to MeOH to EtOH while τ_{ji} remains strongly positive. The introduction of the association term through the aNRTL model shifts most τ parameters in the positive direction, as the attractive forces of association are captured by the association term. The negative shift in τ_{ij} from NRTL to aNRTL for fructose is a result of including the combinatorial (Flory-Huggins) term while the effects of association are almost negligible. The solubility parameters are similar for both models and are consistent with the thermodynamic properties of each sugar, reflecting the fundamental nature of solid solubility.

The following subsections cover the results for each of the sugars in turn, then compare model predictions to experimental data for multi-sugar systems.

Glucose

Figure 3 includes a comparison of model predictions to experimental VLE data for the glucose-water system. Both models effectively capture the range of experimental data, with the aNRTL model performing slightly better at higher temperatures and glucose mass fractions.

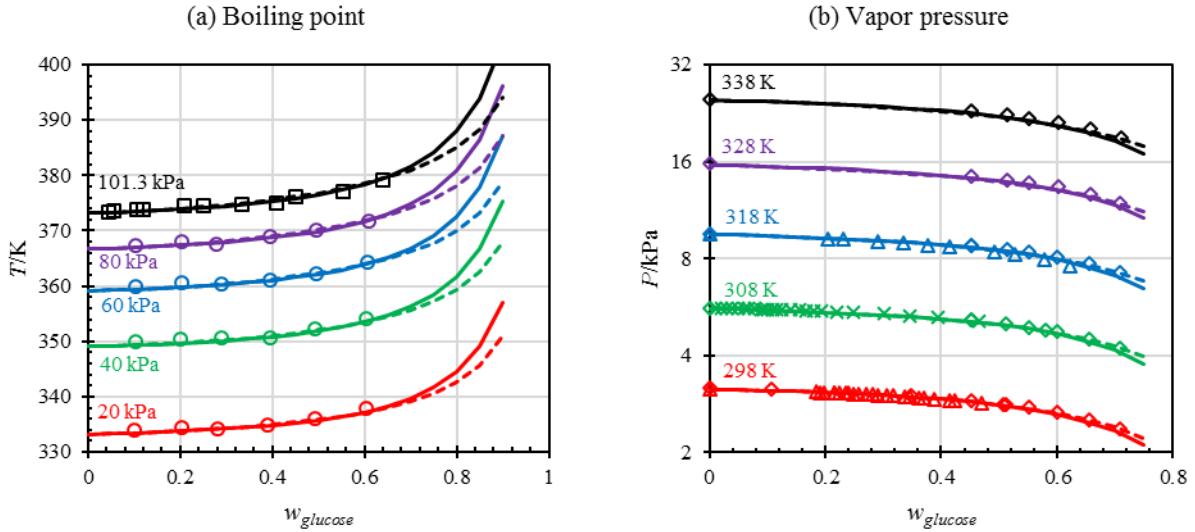

Figure 3: (a) Boiling point elevation and (b) vapor pressure of water with different mass fractions of glucose, including both the (—) NRTL and (- -) aNRTL model and data from (□) Abderafi and Bounahmidi,⁴² (○) Maximo et al.,¹⁶ (◇) Taylor and Rowlinson,⁴¹ (△) Cooke et al.,¹⁸ and (×) Ebrahimi and Sadeghi.⁸

Figure 4 compares model results and experimental data for solubility of glucose in select water-EtOH mixed-solvents. The solubility of glucose in pure water is exactly captured by both models. Even after the exclusion of some data sets, the data for water-EtOH mixed-solvents are not completely consistent. Particularly due to the very low solubility of most sugars in EtOH, it is not surprising that individual data sources and the models themselves have a high degree of relative error when the solvent has high EtOH concentrations. Considering these inconsistencies, both models perform well at matching the solubility of glucose in water-EtOH mixed-solvents within the range of the data. The aNRTL model is an improvement over the NRTL model when it comes to matching the trends present in the data sets across the entire range of ethanol concentrations. The aNRTL model predicts a consistent reduction in solubility as temperature decreases

(reciprocal temperature increases), while the NRTL model shows much less of an effect, especially for systems with higher water-to-EtOH ratios.

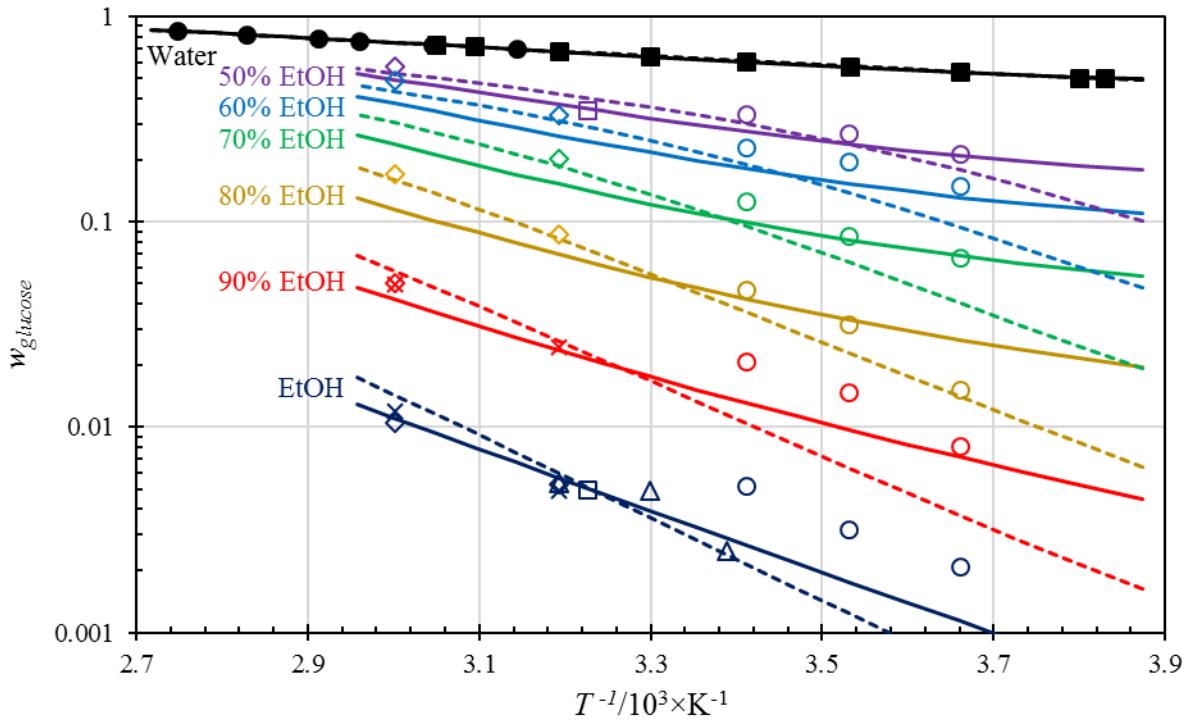

Figure 4: Mass solubility of glucose in various mass fraction water-EtOH solutions, including both the (—) NRTL and (- -) aNRTL model, and data from (■) Young,³⁷ (●) Jackson and Silsbee,³⁵ (○) Gong et al.,¹³ (△) Montanes et al.,¹⁷ (◇) Peres and Macedo,²¹ (□) Bouchard et al.,⁴⁸ and (×) Leontarakis et al.¹⁴

Figure 5 compares model results and experimental data for glucose solubility in the water-MeOH and MeOH-EtOH mixed-solvents. Both models represent the data reasonably well, once again considering the spread of the available data, with the aNRTL model being a slight improvement in capturing all but the outlying data of Montanes et al.¹⁷

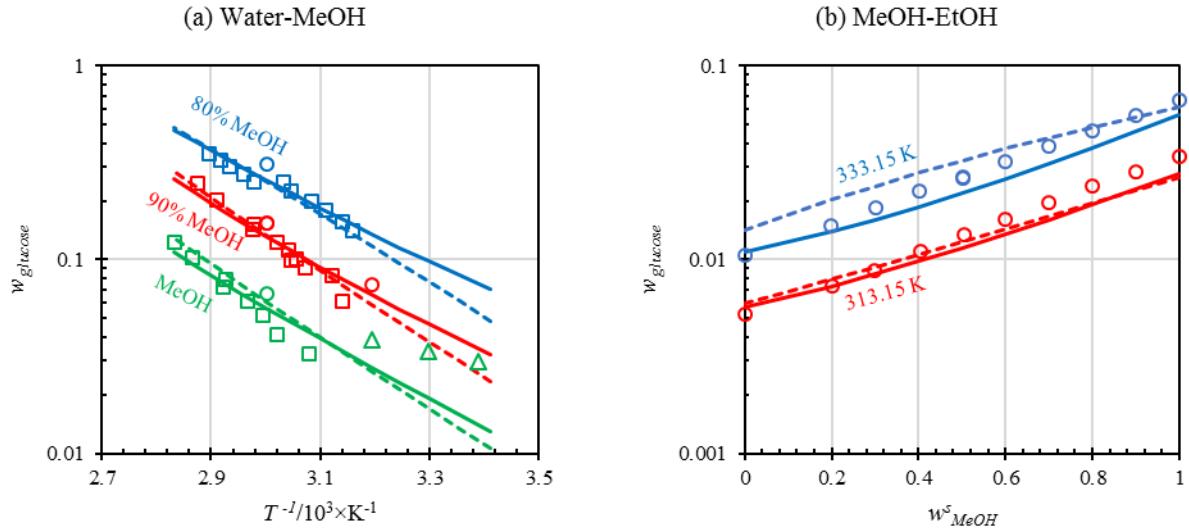

Figure 5: Solubility of glucose in different mass fractions of (a) water-MeOH and (b) MeOH-EtOH solutions, including the (—) NRTL and (- -) aNRTL model and data from (○) Peres and Macedo,²³ (△) Montanes et al.,¹⁷ and (□) van Putten et al.⁴⁷ w^s is mass fraction in the solute-free solvent.

Fructose

Figure 6 includes a comparison of model predictions to experimental VLE data for the fructose-water system. Both models effectively capture the range of experimental data, although the aNRTL model gives slightly better results at higher temperatures and fructose mass fractions.

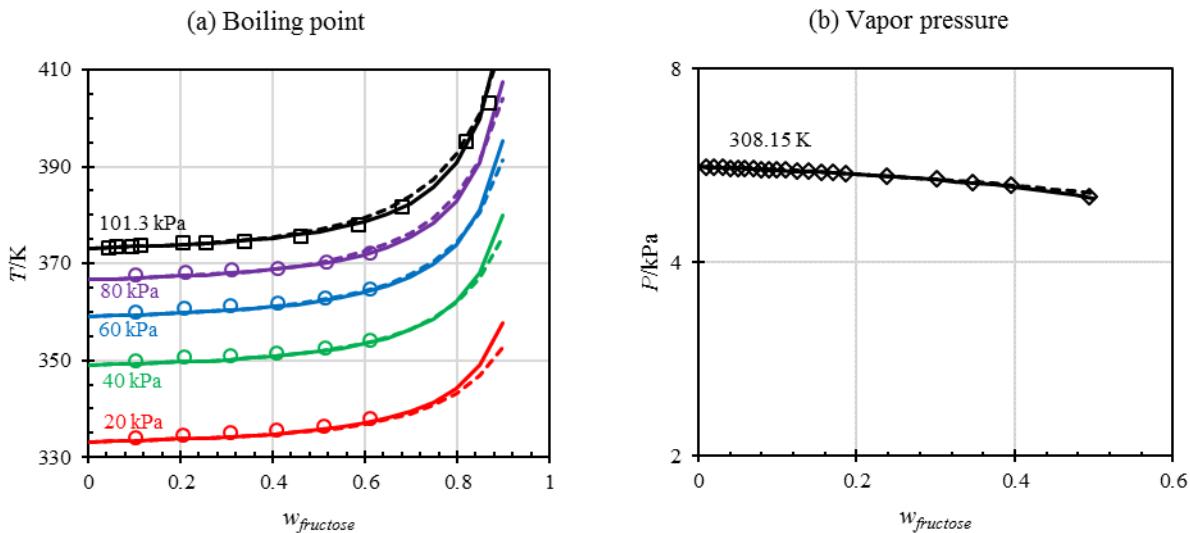

Figure 6: (a) Boiling point elevation and (b) vapor pressure of water with different mass fractions of fructose, including both the (—) NRTL and (- -) aNRTL model, and data from (□) Abderafi and Bounahmidi,⁴² (○) Maximo et al.,¹⁶ (◇) Ebrahimi and Sadeghi.⁸

Figure 7 compares model results and experimental data for the solubility of fructose in water-EtOH mixed-solvents. Fructose is significantly more soluble in alcohols than glucose or sucrose and is reported to have much higher solubility at higher temperatures. This increased solubility in alcohols supports the low calculated association strength, since the alcohols also contain non-associating regions that set them apart from water, which is made up entirely of hydrogen bond donor and acceptor sites. Both models capture the solubility of fructose in pure water. Since fructose has very weak association strength, there is little difference between the models when predicting the solubility of fructose in EtOH-water mixed-solvents, although the aNRTL model shows a slight improvement in pure EtOH and at higher water concentrations.

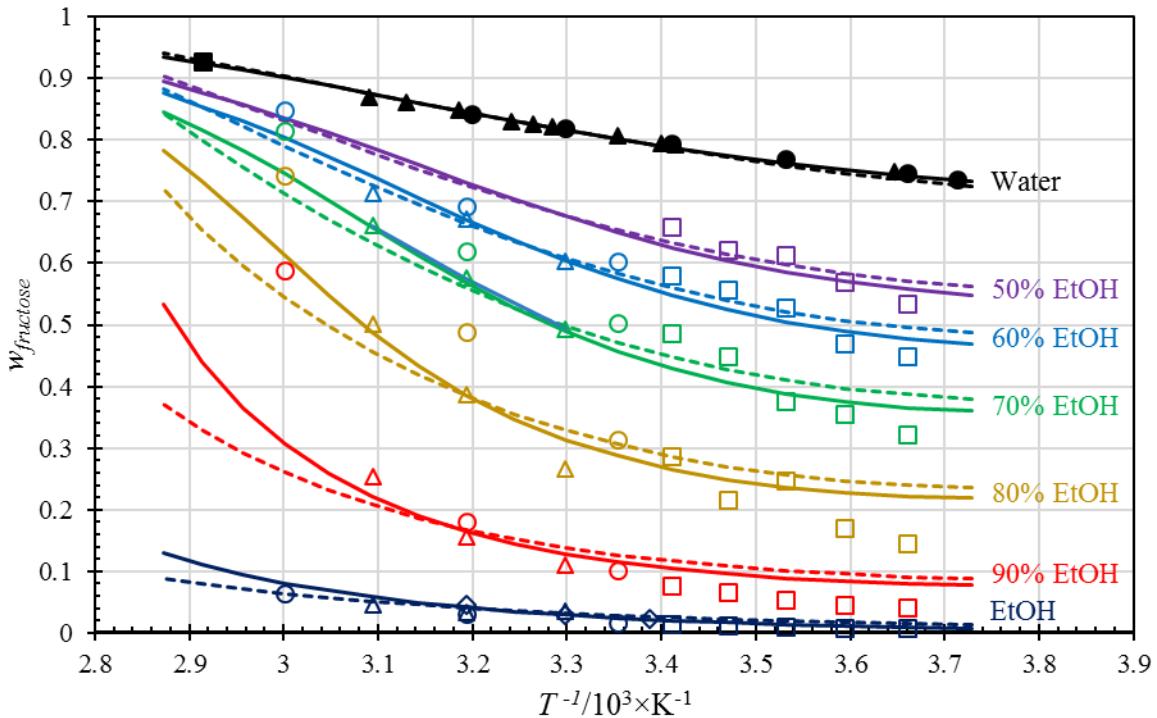

Figure 7: Solubility of fructose in various mass fraction water-EtOH solutions, including both the (—) NRTL and (---) aNRTL model, and data from (●) Young et al.,³⁸ (▲) Vasatko and Smelik,⁵⁰ (■) Abed et al.,¹² (○) Macedo and Peres,¹⁵ (△) Flood et al.,²⁴ (◇) Montanes et al.,¹⁷ and (□) Gong et al.¹³

Figure 8 compares model predictions to experimental data for fructose solubility in water-MeOH and MeOH-EtOH mixed-solvents. Neither model seems to have an advantage when describing both systems, with the NRTL model performing better under certain conditions and the aNRTL performing better under others.

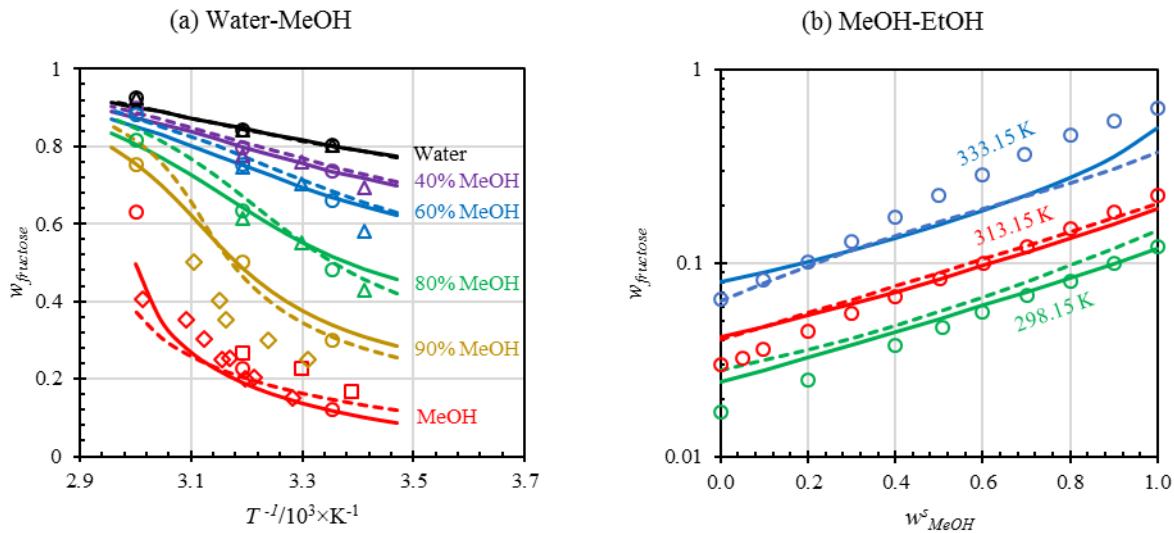

Figure 8: Solubility of fructose in various mass fraction (a) water-MeOH and (b) MeOH-EtOH solutions, including the (—) NRTL and (- -) aNRTL model and data from (○) Macedo and Peres,¹⁵ (□) Montanes et al.,¹⁷ (△) Alavi et al.,¹ and (◇) van Putten et al.⁴⁷ w^s is mass fraction in the solute-free solution.

Sucrose

Figure 9 compares model predictions to experimental data for sucrose-water binary VLE. Both models accurately capture the available data, with the aNRTL model performing better for boiling point elevation of solutions with high sucrose mass fractions.

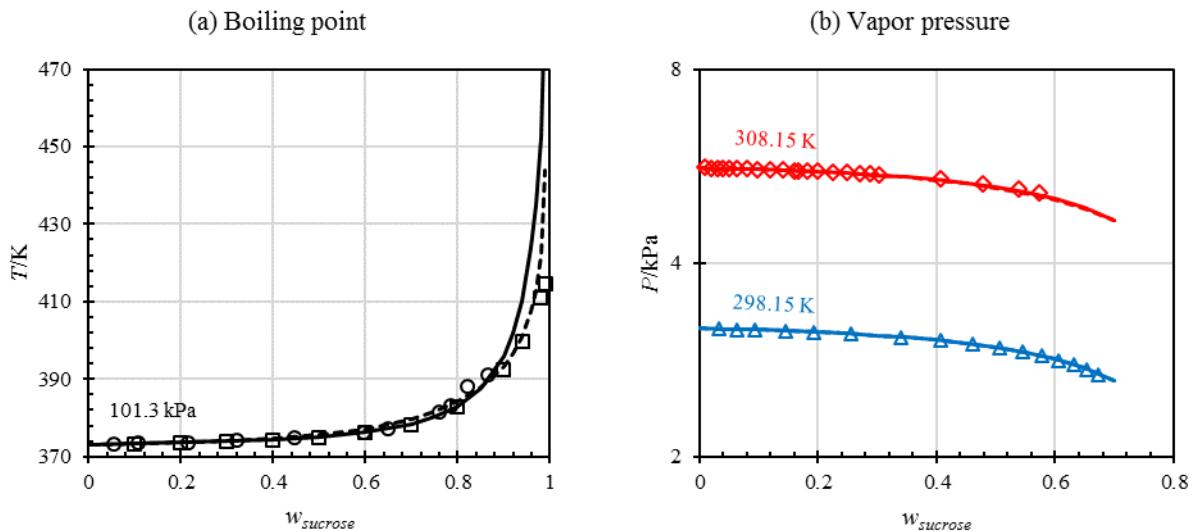

Figure 9: (a) Boiling point elevation and (b) vapor pressure of sucrose-water solutions, including both the (—) NRTL and (- -) aNRTL model, and data from (○) Abderafi and Bounahmidi,⁴² (□) Leschke,⁵³ (◇) Ebrahimi and Sadeghi,⁸ and (△) Robinson et al.⁵²

Figure 10 compares model results and experimental data for the solubility of sucrose in water-EtOH mixed-solvents. Both models exactly match the solubility of sucrose in water and perform well within the variation of the available data for water-EtOH mixed-solvents. Even more so than with glucose, the aNRTL model more closely matches the curvature of the experimental data in all cases except for pure EtOH, where the very low solubility invites a large degree of uncertainty.

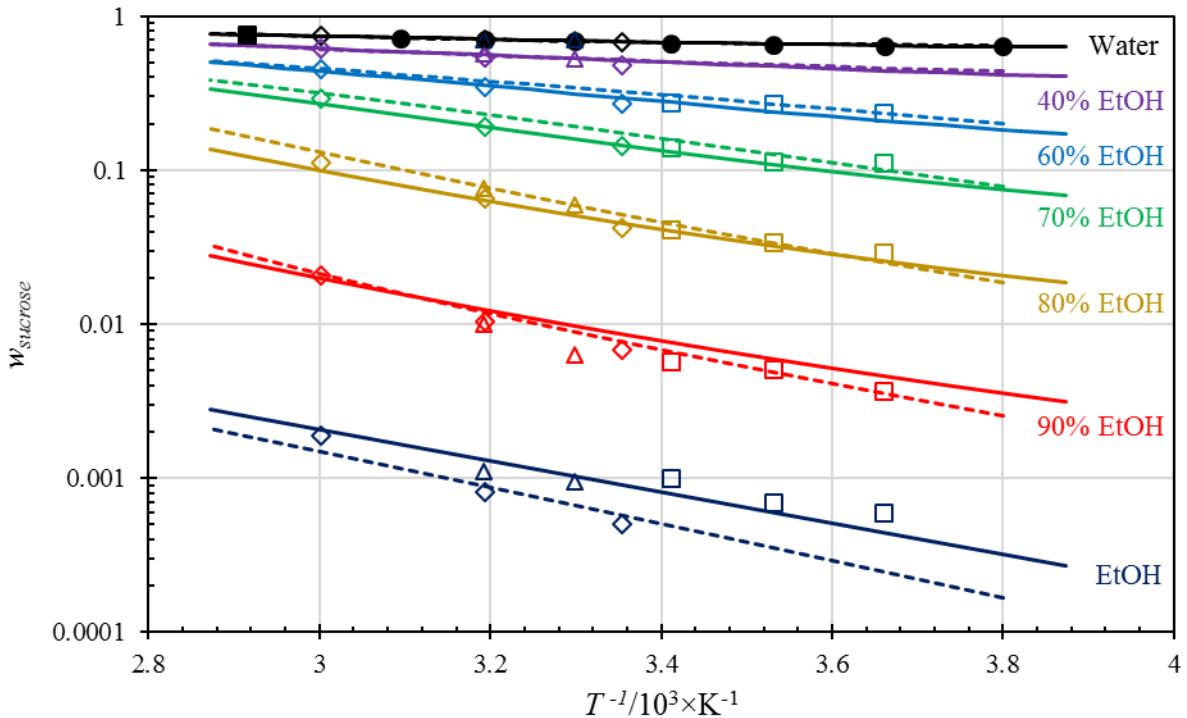

Figure 10: Solubility of sucrose in various mass fraction water-EtOH solutions, including both the (—) NRTL and (---) aNRTL model, and data from (●) Young and Jones,³⁹ (■) Abed et al.,¹² (△) Galvao et al.,⁹ (◇) Peres and Macedo,²² and (□) Gong et al.¹³

Figure 11 compares model predictions to experimental data for sucrose solubility in water-MeOH and MeOH-EtOH mixed-solvents. Both models perform well at capturing the data, with the aNRTL model doing slightly better at matching sucrose solubility in water-MeOH systems and significantly better at matching sucrose solubility in MeOH-EtOH.

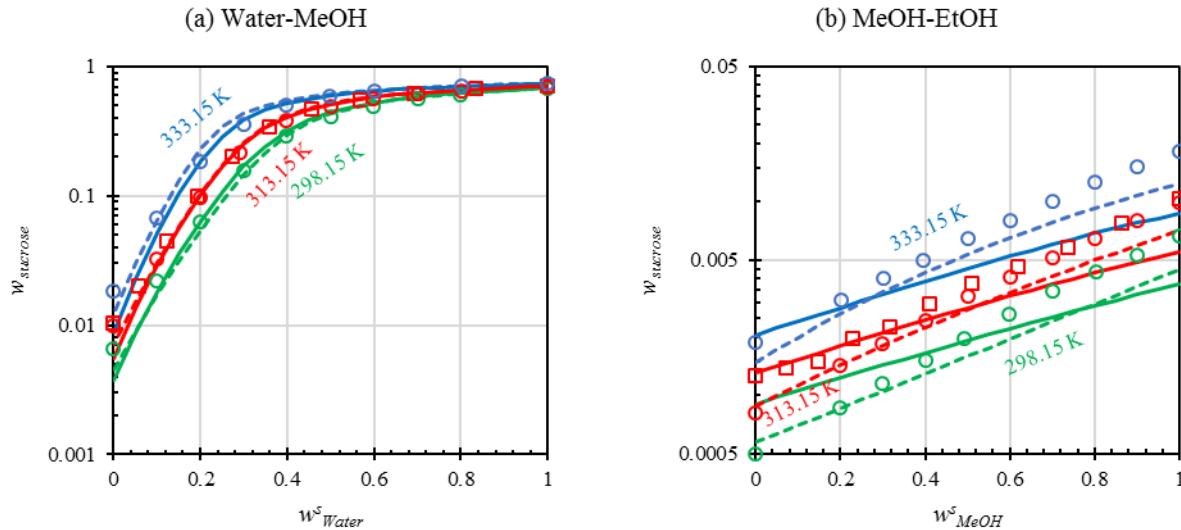

Figure 11: Solubility of sucrose in (a) water-MeOH and (b) MeOH-EtOH solutions, including the (—) NRTL and (- -) aNRTL model and data from (○) Macedo and Peres,¹⁵ and (□) Galvao et al.⁹ w^s is mass fraction in the solute-free solution.

Multi-sugar systems

The utility of these models for overall process modeling hinges on their ability to predict the phase behavior of mixtures containing multiple solutes. To test this ability, the parameters regressed from pure sugar data have been applied to mixtures containing two or more sugars and compared to the available experimental data.

Abderafi and Bounahmidi⁴² measured the boiling points of aqueous solutions of glucose, fructose, sucrose, mixtures of two sugars, and the mixture containing all three. While their data for binary sugar-water systems follow the behavior of similar measurements by other authors and can be well-described by the models, their data for multiple sugars have unusual curvature at low sugar mass fractions. This is particularly obvious in the case of mixtures of glucose and fructose, which each have a similar effect on boiling point elevation. It is unexpected that combining the two

might result in a significantly higher boiling point rise at low mass fractions than either of the substituent species, then level off and then follow the expected trends at high mass fractions. In solutions of sugar mixtures that contained sucrose, the sucrose was present in 20:1 mass ratio to the other sugar(s). This causes the predicted boiling point to be close to the boiling point of pure sucrose, while the reported boiling point rise frequently exceeded that caused by any of the sugars on their own. It is possible that the sugars, especially sucrose, degraded to some extent at the experimental conditions. In spite of these irregularities, both models capture the overall trends of the data as seen in **Figure 12**.

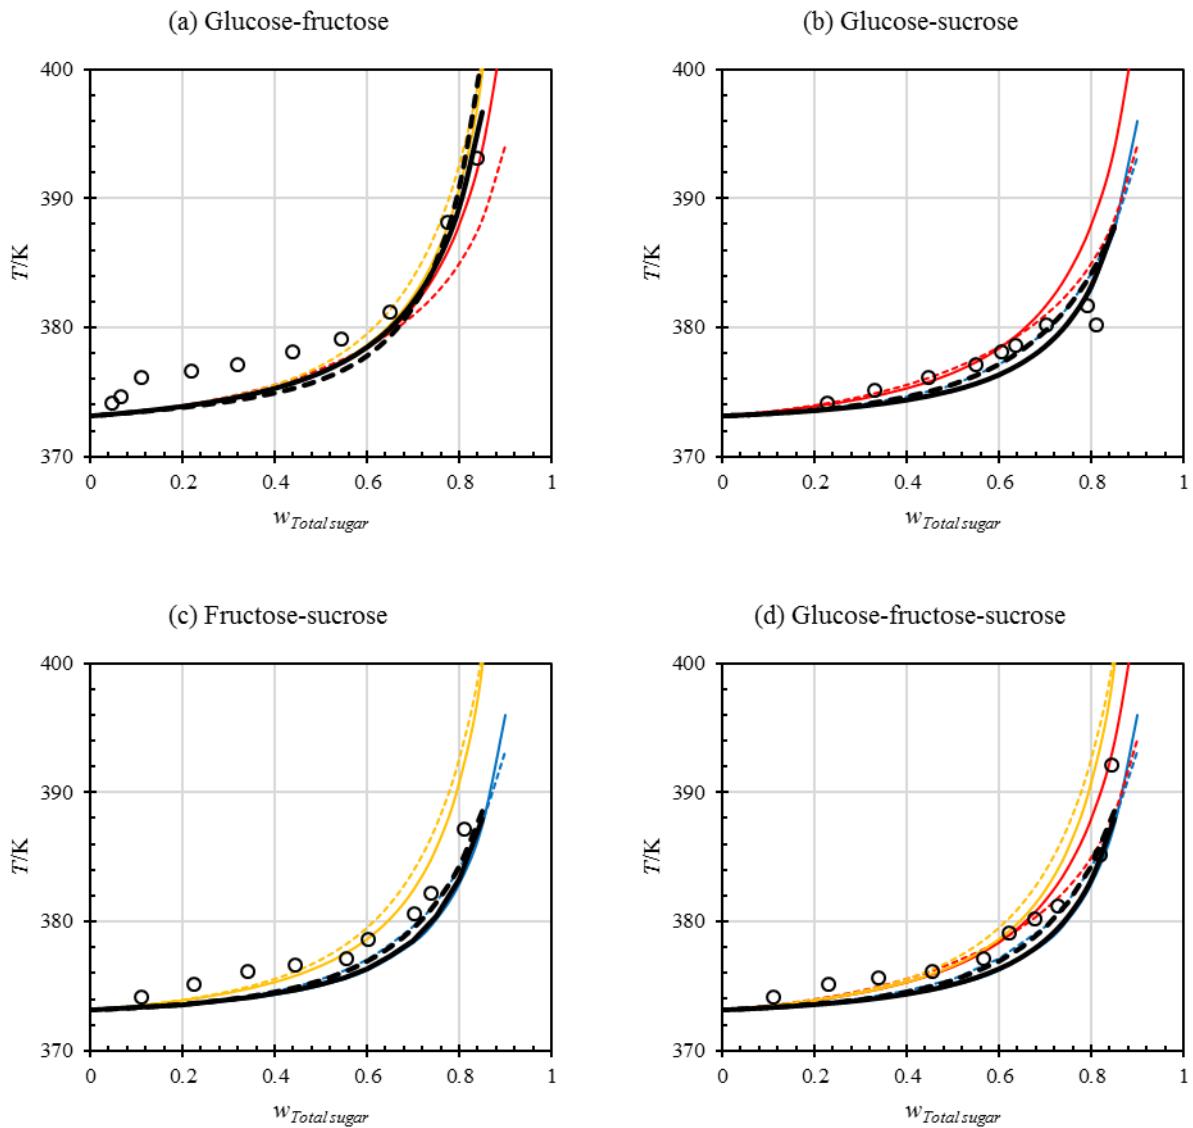

Figure 12. Boiling point elevation of (a) glucose+fructose(1:1)-, (b) glucose+sucrose(1:20)-, (c) fructose+sucrose(1:20)-, and (d) glucose+fructose+sucrose(1:1:20)-water solutions (mass ratios), including the (—) NRTL and (- -) aNRTL model and data from (○) Abderafi and Bounahmidi.⁴² Colored lines indicate the boiling point rise accurately predicted by each model for the pure sugars as a reference: red lines refer to glucose, orange to fructose, blue to sucrose, and black to total sugar.

Kelly³⁶ and Abed et al.¹² reported the solubility of mixtures of glucose or fructose and sucrose in water at 303.15 and 343.15 K, respectively. The models both accurately predict the solubility of each sugar in the mixture, as seen in **Figure 13**. Both models capture the invariant point for the glucose-sucrose system, the inverted “peak” in total sugar solubility observed where both sugars are found in the solid phase. To the left and right of this point, the sugar in the solid phase corresponds to the left and right single-sugar system, respectively. For example, to the left of the invariant point in **Figure 13(b)**, fructose is in the solid phase, while to the right of the invariant point sucrose is in the solid phase. As observed by the experimentalists, the location of the invariant point corresponds to the relative solubility of the two sugars, with the similarly soluble glucose and fructose having an invariant point where the dissolved mass of the sugars is roughly equal, while the invariant point of the fructose-sucrose system is in a location with higher fructose mass fraction.

The NRTL model closely captures the invariant point for the fructose-sucrose system, while the aNRTL model predicts the invariant point shifted to the right with a very indistinct local maximum. As the aNRTL model performs so well overall, and accurately predicts the invariant point for glucose-sucrose and fructose-glucose mixtures, it seems that this particular combination is an outlier of model performance. The most likely cause is that the great difference in association strength causes a slight offset in the predicted solubility of each sugar, which is amplified when adding them together to calculate the total solubility.

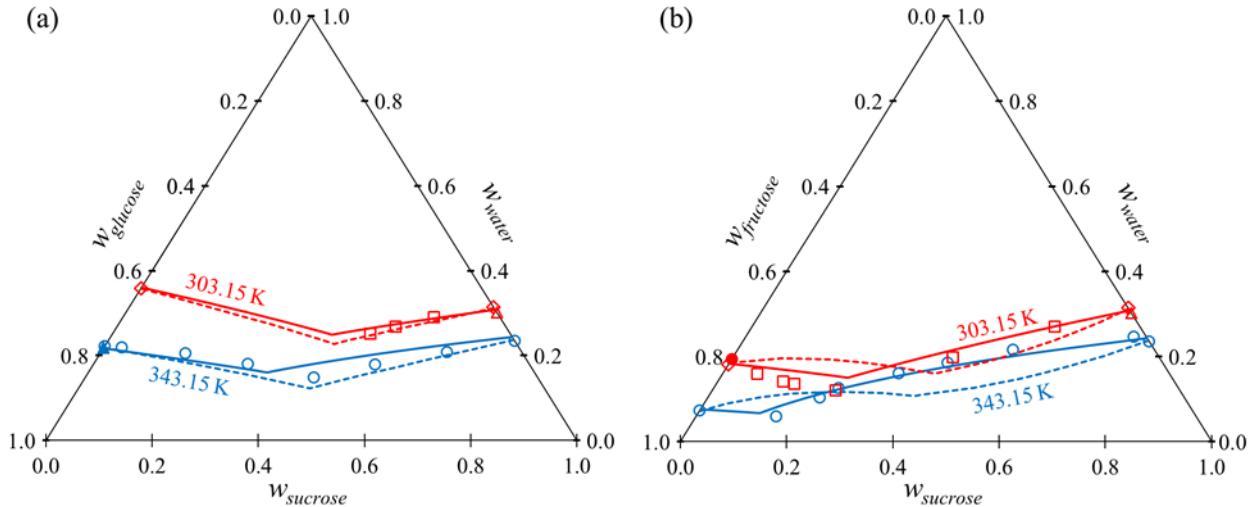

Figure 13: Mutual solubility of (a) glucose+sucrose and (b) fructose+sucrose, including the (—) NRTL and (- -) aNRTL models and data from (○) Abed et al.¹², (□) Kelly³⁶, (◇) Young et al.³⁷⁻³⁹, (△) Galvao et al.⁹, (▲) Jackson and Silsbee,³⁵ and (●) Alavi et al.¹

Flood and Puagsa⁵⁷ measured the solubility of glucose-fructose dissolved in three EtOH-water solutions at 303.15 K. **Figure 14** compares the model results to experimental data for these systems and systems with higher concentrations of water. The models are offset from the data at 40% and 60% EtOH solutions, perhaps due to the presence of metastable glucose·monohydrate³⁴ in the solid phase. There is no corroborating data for pure glucose in these solvent mixtures at 303.15 K, but the models are consistent with the other available data around this temperature. When the model and Flood and Puagsa's⁵⁷ data agree with the pure glucose solubility, as for 80% EtOH solution the predictions are within the spread of the data. Both models predict the invariant point for mixtures of the two sugars consistent with the maximum measured solubility.

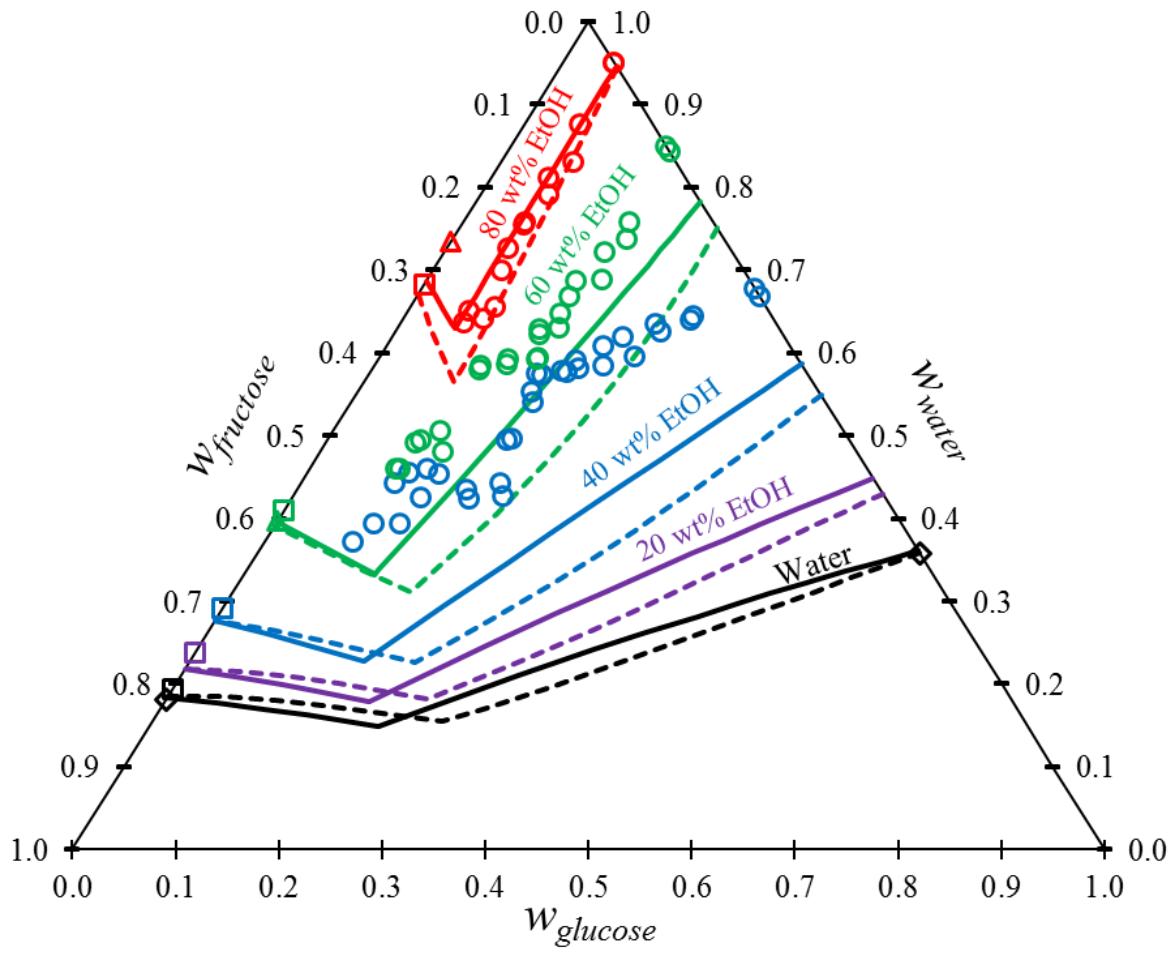

Figure 14: Mutual solubility of glucose-fructose in EtOH-water solutions at 303.15 K, including the (—) NRTL and (---) aNRTL models and data from (○) Flood and Puagsa⁵⁷, (□) Alavi et al.¹, (△) Flood et al.²⁴, and (◇) Young et al.³⁷⁻³⁸

CONCLUSIONS

Both models presented here provide an accurate description of the experimental data in all but a few outlying cases. The NRTL model works well because, due to the high concentration of hydroxyl groups on each of the sugars, water, and alcohols, the species are quite similar from an interaction standpoint. Accordingly, the NRTL model may be used to adequately describe the phase equilibrium of sugar-containing systems when aNRTL parameters are not available for the

other components and it is not practical to regress them. The inclusion of the association term provides an improvement over the base NRTL model that is most effective for sucrose, effective for glucose, and least effective for fructose. The aNRTL model is thus able to better predict the solubility of glucose and sucrose, consistently matching the curvature of the data. Both models demonstrate the ability to accurately predict the phase behavior of systems containing multiple sugars from only sugar-solvent binary parameters. This bodes well for the continued use of NRTL, and especially aNRTL, to describe other sugars, such as xylose, and the anhydrous derivatives of xylose and glucose, xylosan and levoglucosan, which are important products of biomass pyrolysis. The well-defined association parameters and consistency of the interaction parameters, in their progression from water to MeOH to EtOH, are promising signs that these models can be readily extended to include additional solvents and similarly structured sugars. Additional measurements of the boiling point rise of multi-sugar systems would be needed to validate the single set of available data. To further extend the predictive ability of aNRTL requires additional data for the phase equilibrium of sugars in non-associating solvents. With the recently developed association-NRTL-Segment Activity Coefficient (aNRTL-SAC) model,³¹ the phase behavior of each sugar in a few solvents can be used to regress sugar-specific parameters that will apply in any solvent or solvent mixture without any additional regression.

Assignment of standard deviations for data regression

Especially when dealing with older data, it is common for authors not to report the error in their measurements. When a standard deviation is given, there is little consistency between authors in how they account for error, if they describe their methods at all. To avoid bias toward the data that happens to report the lowest error, the authors of this work assigned standard values of error to the experimental measurements. These standards were relaxed or tightened to account for data sets that deviate from comparable sets or data points that had particularly small values. For example, the boiling point measurements of Abderafi and Bounahmidi¹ were given a higher standard deviation as their data sets tended to deviate from other sets of boiling point data (Maximo et al.², Leschke³). As another example, due to the low solubility of glucose and sucrose in methanol and ethanol, some data sets were given 20-30% standard deviation when the concentration of sugar dropped below 10% of the standard assigned value of 0.005 fraction.

Vapor-liquid equilibrium (VLE) data that was collected at a constant temperature or pressure was given a standard deviation of 0 for the respective state variable. The sugars were assumed to be nonvolatile, so the concentrations of sugar in the vapor phase for VLE measurements were set to 0 with a standard deviation of 0. For activity of water data, the activity coefficient of the sugar was left blank and given a standard deviation of 100%.

Every data set used for data regression is included in the Microsoft Excel workbook in the Supplemental Information in the same format as it was entered into Aspen Properties.⁴ The source of each data set is identified by “Author List (Year)” at the top of each data table, with the reader referred to the references list in the manuscript for citation details. If needed, a source journal abbreviation is included to differentiate between referenced documents published by the same author(s) in the same year. For each data set, the first column represents the usage of the numbers in that row: STD-DEV (assignment of standard deviation), DATA (data used in regression), and Ignore (applied to very few points that

were rejected for abnormal behavior). The rows marked STD-DEV apply to all of the rows beneath them, with any new STD-DEV superseding the last. For any system with C components, C-1 component concentrations are assigned standard deviations, with the last component concentration automatically calculated and assigned a standard deviation of 0. All in all, the 1202 data points used in data regression contained approximately 2950 values.

Error analysis

The Aspen Properties regression program calculates the weighted sum of squares (*WSS*) and the residual root mean squared error (*RMSE*) as a measure of goodness of fit for regressed property model parameters (see manuscript for definitions). With a large data set, these measures become desensitized to the addition of potentially spurious parameters. Information criteria, which balance the likelihood function against the number of parameters, provide a way to avoid this problem. Three information criteria were calculated in addition to the *WSS* and *RMSE* reported by Aspen Properties. These were the Mallows information criterion (*MIC*),⁵

$$MIC = (K - q) \left(\frac{SSE}{SSE_q} \right) + 2n - K \quad (S-1)$$

the Akaike information criterion (*AIC*),⁶

$$AIC = K \ln \left(\frac{SSE}{K} \right) + 2n \quad (S-2)$$

and the Bayesian information criterion (*BIC*).⁶

$$BIC = K \ln \left(\frac{SSE}{K} \right) + n \ln K \quad (S-3)$$

where *K* is the number of data points, *n* is the number of parameters, *q* is the number of parameters of the full (reference) model, *SSE* is the sum of squared error, and *SSE_q* is the sum of squared error for the reference model with *q* parameters. As mentioned in the manuscript, *SSE* was replaced by *WSS* (automatically calculated and reported by Aspen Properties) for comparison of the models. This means that the information criteria reported here are modified versions, and because of this, the values of the modified *AIC* and *BIC* are often negative.

Table S-1 presents the results of the statistical analysis of the models. The aNRTL with variable *r* was chosen as the full, *n* = *q*, model for comparison of the *MIC*. All four measures – *RMSE* and the three modified information criteria – agree that the aNRTL (with variable *r*) model provides the best fit of the three options investigated. Fixing *r* reduces the number of adjustable parameters, but significantly increases the sum of squares and, thus, the values of the information criteria.

Supporting Information for Modeling Phase Equilibrium of Sugars in Mixed Solvents

Table S-1: Comparison between measures of goodness of fit for the three model alternatives (*MIC*, *AIC*, and *BIC* modified to use *WSS* in place of *SSE*).
